**Diastolic Spontaneous Calcium Release From the Sarcoplasmic Reticulum Increases Beat-to-Beat Variability of Repolarization in Canine Ventricular Myocytes After β-Adrenergic Stimulation**

Daniel M. Johnson,* Jordi Heijman,* Elizabeth F. Bode, David J. Greensmith, Henk van der Linde, Najah Abi-Gerges, David A. Eisner, Andrew W. Trafford, Paul G.A. Volders

**Rationale:** Spontaneous Ca\(^{2+}\) release (SCR) from the sarcoplasmic reticulum can cause delayed afterdepolarizations and triggered activity, contributing to arrhythmogenesis during β-adrenergic stimulation. Excessive beat-to-beat variability of repolarization duration (BVR) is a proarrhythmic marker. Previous research has shown that BVR is increased during intense β-adrenergic stimulation, leading to SCR.

**Objective:** We aimed to determine ionic mechanisms controlling BVR under these conditions.

**Methods and Results:** Membrane potentials and cell shortening or Ca\(^{2+}\) transients were recorded from isolated canine left ventricular myocytes in the presence of isoproterenol. Action-potential (AP) durations after delayed afterdepolarizations were significantly prolonged. Addition of slowly activating rectifier K\(^{+}\) current (I\(_{\text{ks}}\)) blockage led to further AP prolongation after SCR, and this strongly correlated with exaggerated BVR. Suppressing SCR via inhibition of ryanodine receptors, Ca\(^{2+}\)/calmodulin-dependent protein kinase II inhibition, or by using Mg\(^{2+}\) or flecainide eliminated delayed afterdepolarizations and decreased BVR independent of effects on AP duration. Computational analyses and voltage-clamp experiments measuring L-type Ca\(^{2+}\) current (I\(_{\text{CaL}}\)) with and without previous SCR indicated that I\(_{\text{ks}}\) was increased during Ca\(^{2+}\)-induced Ca\(^{2+}\) release after SCR, and this contributes to AP prolongation. Prolongation of QT, T\(_{\text{peak}}\)-T\(_{\text{end}}\) intervals, and left ventricular monophasic AP duration of beats after aftercontractions occurred before torsades de pointes in an in vivo dog model of drug-induced long-QTI syndrome.

**Conclusions:** SCR contributes to increased BVR by interpersed prolongation of AP duration, which is exacerbated during I\(_{\text{ks}}\) blockade. Attenuation of Ca\(^{2+}\)-induced Ca\(^{2+}\) release by SCR underlies AP prolongation via increased I\(_{\text{CaL}}\). These data provide novel insights into arrhythmogenic mechanisms during β-adrenergic stimulation besides triggered activity and illustrate the importance of I\(_{\text{ks}}\) function in preventing excessive BVR. (*Circ Res.* 2013;112:246-256.)

**Key Words:** action potentials   arrhythmia   β-adrenergic receptors   calcium   sarcoplasmic reticulum

Enhanced cellular Ca\(^{2+}\) load, for example, during β-adrenergic receptor (βAR) stimulation, results in augmentation of Ca\(^{2+}\) release from the sarcoplasmic reticulum (SR), larger Ca\(^{2+}\) transients (CaT), and enhanced contractile force. Under certain conditions, Ca\(^{2+}\) load is increased beyond a certain threshold, leading to spontaneous Ca\(^{2+}\) release (SCR) from the SR during diastole. In this diastolic leak causes a transient inward current (I\(_{\text{L}}\)), causing delayed afterdepolarizations (DADs) mainly attributable to activation of the electrogenic Na\(^{+}\)-Ca\(^{2+}\) exchanger, with the Ca\(^{2+}\)-activated Cl\(^{-}\) current (I\(_{\text{CaCl}}\)) contributing in some species. Previous work has shown that both DADs and early afterdepolarizations (EADs) may share a common mechanism, at least during βAR stimulation and Ca\(^{2+}\) overload, namely SCR-induced currents. Both types of afterdepolarizations have been incriminated in the formation of ventricular tachycardia via triggered activity (TA) and by increasing dispersion of repolarization. Beat-to-beat variability (BVR) of repolarization duration occurs as an apparently random alteration in repolarization duration and can be observed at all levels from the action potential to first decision for all original research papers submitted to *Circulation Research* was 12.5 days. potential (AP) of the single cardiac myocyte to the QT interval on the body surface.7–9 Exaggerated BVR has been reported to be a more reliable indicator of arrhythmogenic risk than repolarization prolongation, per se, at least in several experimental ventricular tachycardia models10–12 and in selected human subjects.8,13

Although BVR has been investigated in multiple studies, the mechanisms underlying this phenomenon at the single-cell level remain to be fully elucidated. Pharmacological interventions influencing ion channels that operate during the AP plateau can markedly alter BVR.7,14 Despite the fact that inhibition of the slowly activating delayed rectifier K⁺ current (Iₖₛ) alone has minimal effects on both cellular AP duration (APD) and BVR,14 we recently have shown that during increased Ca²⁺ loading in myocytes subjected to blockade of Iₖₛ in combination with βAR stimulation, BVR is significantly enhanced, even before the occurrence of EADs and TA.14

In the present study, we investigated the relationship between SCR and BVR using a combined experimental and computational approach in both canine ventricular myocytes and in situ hearts subjected to βAR stimulation. We show that SCRs not only lead to Iₖₛ and DAD formation but also lead to a prolonged duration of AP via increased L-type Ca²⁺ current (I_{CaL}), which in turn leads to increased BVR when analyzing multiple consecutive APs. Pharmacological interventions that inhibit SCR (either with reduced or with preserved systolic contraction) prevent this SCR-associated AP prolongation and reduce BVR.

**Methods**

This investigation conformed to the Guide for the Care and Use of Laboratory Animals published by the United States National Institutes of Health (National Institutes of Health Publication 85-23, revised 1996). Animal handling was in accordance with the European Directive for the Protection of Vertebrate Animals Used for Experimental and Other Scientific Purposes (86/609/EU). Full details of methods, solutions, and interventions used are given in the online-only Data Supplement accompanying this article. A brief summary of the main aspects is provided.

**Myocyte Isolation and Electrophysiology**

Canine left ventricular (LV) myocytes were isolated as previously described.11 Transmembrane APs were recorded at ≈37°C using high-resistance (30–60 MΩ) glass microelectrodes filled with 3 mol/L KCl. Myocyte contractions were recorded with a video edge motion detector.

**Calcium Measurement**

We used the perforated patch-clamp technique under current-clamp or voltage-clamp control as previously described.16 Myocytes were stimulated to elicit APs (current clamp) or I_{CaL} (voltage clamp). Changes in intracellular Ca²⁺ concentration ([Ca²⁺]) were measured using Fluo-3 or Fura-2 AM.16

**Computational Analysis**

A recent model of the canine ventricular myocyte electrophysiology including βAR stimulation11 was extended with a method to induce diastolic SR Ca²⁺ release in 1 of 2 identical Ca²⁺ domains in a controlled fashion (Online Figures I and II). Simulations were performed in single cells as well as in a 1-dimensional homogeneous strand or 2-dimensional tissue of electrically coupled cells to determine the effects of diastolic Ca²⁺ release in the presence of electrotonic coupling.

**In Vivo Dog Model of Drug-Induced Long-QT1 Syndrome**

Torsades de Pointes (TdP) arrhythmias were induced in an in vivo dog model of long-QT1 (LQT1) syndrome as previously described.11 ECG, LV pressure, and LV monophasic APs (LV MAPs) were recorded throughout the experiments and analyzed offline.

**Data Analysis and Statistical Comparisons**

APD was quantified at 90% repolarization. BVR was quantified as variability of APD using the formula Σ(ΔAPD)²/Δn, where APD is the AP duration of APs in the absence of TA.10 DADs were detected with a semiautomated method using a custom software script (online-only Data Supplement). When applicable, data were reported as means±SEM of number experiments and significance was tested with either t test or 1-way ANOVA. Differences were considered statistically significant if P<0.05.

**Results**

DADs Prolong Subsequent APs and Increase BVR

Under baseline conditions, a small beat-to-beat APD variability was observed (Figure 1A, left). βAR stimulation with isoproterenol (ISO) shortened APD and enhanced contraction (Figure 1A, middle). In the majority of cells, 100 nmol/L ISO caused DADs during pacing at 1000-ms cycle length (CL). APs after a DAD were prolonged, leading to increased BVR attributable to interspersed occurrence of normal and prolonged APs (Figure 1A, middle). Pharmacological inhibition of Iₖₛ by HMR1556 (500 nmol/L) in the presence of ISO further prolonged APD and increased BVR (Figure 1A, right). In separate experiments, CaT were recorded together with APs after HMR1556 and ISO. HMR1556 alone did not increase the CaT amplitude or lead to any SCR events. The combination of HMR1556 and ISO, however, led to large increases in CaT amplitude and SCR, as expected.15 APs after SCR were prolonged and had a reduced systolic CaT amplitude compared with those in which no diastolic release preceded the AP, indicating reduced SR Ca²⁺ load at the start of the AP (Figure 1B), consistent with the reduced cell shortening after an aftercontraction (Figure 1A).
APD prolongation after a DAD was significantly more pronounced in the presence of ISO plus HMR1556 compared with ISO alone at all CLs (eg, 41±6 ms vs 15±4 ms at CL=1000 ms; P<0.05; Figure 2A), and this coincided with a significant increase in BVR (17±2 ms vs 7±1 ms; P<0.05; Figure 2B). As such, HMR1556 was added in all subsequent experiments in the presence of ISO to maximize effects on APD, essentially creating a cellular model of drug-induced LQT1 syndrome.14

DADs showed typical rate-dependent properties, including increased amplitude and decreased AP–DAD coupling interval at shorter pacing CL, consistent with previous results.19 IKs blockade did not alter rate-dependent DAD properties (Online Figure III).

To determine whether DAD-like membrane-potential changes alone (ie, without underlying alterations in intracellular Ca2+) influenced the subsequent AP, current was injected to induce small alterations in the resting membrane potential (25-mV amplitude, 150-ms duration; Figure 2C, top). There was no significant difference between APDs in the absence or presence of these diastolic pulses (Figure 2D), independent of the timing of the pulse (not shown). In contrast, when these cells were stimulated with HMR1556 plus ISO, DADs occurred and subsequent APD was significantly prolonged (Figure 2C, bottom), indicating that alterations in the subsequent APD were influenced by DAD-related events other than membrane-potential alterations per se.

**Coupling Between the Occurrence of DADs and EADs During β-Adrenergic Stimulation and IKS Blockade**

In addition to DADs, EADs were observed. EADs occurred predominantly at 500-ms CL and exclusively in the presence of HMR1556 plus ISO. We observed early aftercontractions preceding EAD upstrokes by 21±5 ms (Figure 3A and 3C),5 consistent with the observations by Zhao et al10 in rabbit ventricular myocytes challenged with ISO and the ICaL agonist Bay K 8644, suggesting a role of SCR for EAD formation under these specific conditions.5 We quantified the occurrence of DADs in the beats preceding an EAD and found that DADs were significantly more likely to occur in the 2 beats directly preceding an EAD (53% and 95% of APs) compared with average DAD occurrence for all beats (34%; Figure 3A, bottom). Figure 3B shows the responses during ISO alone.

**Blockade of Spontaneous SR Ca2+ Release Reduces BVR**

We sought to further investigate how eliminating SCR would affect APD and BVR. Blockade of the ryanodine receptor (RYR) with ryanodine eliminated DADs and led to a drastic reduction in BVR, despite leading to an increased APD (Figure 4A and 4B). APD prolongation under these conditions was not associated with any arrhythmogenic events. A drastic...
reduction in systolic contraction was also seen, as expected, indicating that blockade of RyRs was achieved effectively.

Tetracaine reduces the open probability ($P_o$) of RyR, leading to a decrease in the frequency of SCR in unstimulated rat ventricular myocytes and the abolishment of ISO-induced SCR in voltage-clamped rat ventricular myocytes. Similar to ryanodine, tetracaine led to an elimination of DADs in our experiments and a reduction in BVR at all CLs. However, unlike ryanodine, cell shortening remained largely unaltered, indicating that systolic Ca$^{2+}$ release was largely intact (Figure 4C and 4D).

To determine the effects of increasing the $P_o$ of RyRs, as opposed to decreasing it, we used low concentrations of caffeine (maximally 500 µmol/L). Under these conditions, the percentage of APs showing DADs was increased at all CLs. Interestingly, this led to a significant decrease in BVR compared with HMR1556 and ISO alone, because DADs occurred before every AP (Figure 5, rightmost grey bars).

Several studies have shown that Ca$^{2+}$/CaMKII is an important signaling molecule affecting Ca$^{2+}$-induced Ca$^{2+}$ release and that its inhibition can be antiarrhythmic. Curran et al demonstrated that SR Ca$^{2+}$ leak during βAR stimulation is mediated by Ca$^{2+}$/calmodulin-dependent protein kinase II (CaMKII). In our experiments, inhibition of calmodulin using W7 reduced DAD incidence in all cells (from 44% to 8% at 1000 ms CL; $P<0.05$) and completely abolished them in 3 of 7 cells. The decrease in DAD occurrence was paralleled by a decrease in BVR. APD was unaltered by W7, and systolic contractions remained intact. Application of the CaMKII inhibitor KN93 led to similar results (Figure 5, black bars).

Mg$^{2+}$ has been shown to suppress both EADs and DADs in different models and is used clinically as a first-line agent against TdP. Increasing extracellular [Mg$^{2+}$] from 1 mmol/L to 5 mmol/L abolished DADs induced after HMR1556 and ISO in 4 of 7 cells. In the remaining 3 cells, DAD incidence was significantly reduced. A concomitant reduction in BVR was seen. APDs were not significantly altered, and although systolic contractions were slightly reduced compared with beats that did not show SCR events before Mg$^{2+}$, they remained stable, suggesting that the SR content remained constant (not shown).

Similar results (albeit with reduced APD) were obtained with the class IC antiarrhythmic agent flecainide (Figure 5, striped bars), which has been shown to be effective in preventing catecholaminergic polymorphic ventricular tachycardia because of its effects on RyR and Na$^+$ channels.

**Increases in [Ca$^{2+}$] Can Reinstate SCR Only When Residual RyR Function Is Available**

We hypothesized that increases in [Ca$^{2+}$], after interventions that reduced DAD occurrence would lead to recurrence of SCR and DADs and increase BVR. Therefore, we raised the [Ca$^{2+}$] from 1.8 mmol/L to 3.6 mmol/L after application of ryanodine, tetracaine, or W7. This led to a reinduction of DADs after tetracaine or W7, and to a significant decrease of...
ADP (Online Figure IVA–IVC). However, increasing [Ca\(^{2+}\)]\(_{ib}\), after ryanodine did not lead to DADs, nor did it alter BVR, indicating that RyR function is required for SCR, and without ryanodine did not lead to DADs, nor did it alter BVR, indicating that RyR function is required for SCR, and without it counteracted the repolarization delay. As such, APD prolongation after SCR. This prediction was confirmed under voltage-clamp conditions in native canine ventricular myocytes when the extracellular solution was modified to isolate ICaL (Figure 7). During a voltage step to +10 mV from a holding potential of −80 mV, a significant increase in the integral of ICaL was observed after SCR: ∫ ICaL = 27.9±3.5 nC vs 33.0±3.5 nC in the absence or presence of SCR, respectively (P<0.05).

**Relation Between Aftercontractions, Repolarization Prolongation, and Dispersion and Arrhythmogenesis in the Intact Canine Heart**

To evaluate whether the single-cell mechanisms described above could affect arrhythmogenesis in vivo, we used a canine model of drug-induced LQT1. Application of a bolus of ISO during continuous HMR1556 infusion resulted in aftercontractions exclusively in the LV pressure signal before the development of ventricular premature beats and TdP (Figure 8A). In parallel with the occurrence of aftercontractions, we observed paradoxical QT prolongation during β-adrenergic heart rate acceleration, resulting in a significant increase of the QT interval in the last sinus beats before the extrasystoles triggering TdP (Figure 8B). Similarly, LV MAP duration was significantly prolonged in these beats and a significant increase in T\(_{p-\text{rad}}\)-T\(_{\text{rad}}\) interval was noted (Figure 8B), which could reflect an increased dispersion of repolarization. We focused on repolarization duration by comparing the beats before and after the first notable aftercontraction. QT, LV MAP, and T\(_{p-\text{rad}}\)-T\(_{\text{rad}}\) durations were significantly increased in the beat after the first aftercontraction, whereas the RR intervals were unchanged in HMR1556 (Figure 8C). Furthermore, the ICaL inhibitor verapamil (0.4 mg/kg) prevented TdP induction by ISO during continuous HMR1556 infusion in 5 of 5 animals (Figure 8A), although some ventricular extrasystolic activity still could be observed (Online Figure VIII). Similar chronotropic responses were seen after ISO in the presence of verapamil but, in the absence of aftercontractions, QT, LV MAP, and T\(_{p-\text{rad}}\)-T\(_{\text{rad}}\) prolongation were significantly smaller when compared with HMR1556.
and ISO alone (Figure 8B). These data illustrate the role of Ca²⁺-dependent regional repolarization prolongation for TdP induction in this model.

To further test the hypothesis that SCR at the single-myocyte level can contribute to the QT and Tpeak-Tend interval prolongation seen in vivo, we performed computer simulations of both a homogeneous 1-dimensional strand and a 2-dimensional tissue of electrically coupled myocytes. Consistent with our hypothesis, diastolic SR Ca²⁺ release increased repolarization duration and spatial dispersion of repolarization in both simulations (Figure 8D, Online Figures V–VI), and this effect was completely abolished by inhibition of ICaL CDI (Figure 8D, Online Figure VII).

Discussion

In this study, we elucidated the relationship between SCR, AP prolongation, and BVR in canine LV myocytes and provide arguments for its arrhythmogenic significance in the in vivo beating heart. Our data indicate that under conditions of ISO-induced Ca²⁺ loading, SCR can occur over a wide range of pacing CLs and that APD after SCR is significantly prolonged. Reduced Ca²⁺-induced Ca²⁺ release-dependent inactivation of ICaL after SCR is involved in this AP prolongation. The increase in BVR was strongly dependent on the degree of APD prolongation after SCR. In anesthetized dogs subjected to similar conditions, we observed the occurrence of mounting aftercontractions in parallel with QT, Tpeak-Tend, and LV MAP prolongation just before TdP, which could be prevented by inhibition of ICaL and Ca²⁺ load with verapamil. SCR-related repolarization prolongation was reproduced in multicellular computer simulations. Our data align with recent data showing that local βAR stimulation synchronizes SCR in the normal rabbit heart, leading to Ca²⁺-mediated focal arrhythmia. In the setting of exaggerated spatio-temporal dispersion of repolarization, such focal activity may trigger TdP, as actually observed in the canine model of drug-induced LQT1 syndrome and βAR stimulation.

Previous cellular studies have shown that large CaTs result in abbreviation of APD, whereas a small CaT after SR Ca²⁺ depletion corresponds to prolonged APD. In agreement, we found substantial APD prolongation after application of ryanodine because of (partial) SR Ca²⁺ unloading by SCR. These changes in CDI are sufficient to modulate APD on a beat-to-beat basis over a wide range of CLs. Interestingly, Spencer and Sham reported the opposite effect in guinea pig ventricular myocytes, perhaps because of species differences in the balance of Na⁺-Ca²⁺ exchanger and ICaL. In the present study, we used Ca²⁺-sensitive fluorescent probes and cell shortening as Ca²⁺ indicators. Both measures reflect cytosolic Ca²⁺ levels, which are substantially different from the subsarcolemmal [Ca²⁺] influencing Ca²⁺-activated membrane currents.
The Importance of IKs Blockade

Burashnikov and Antzelevitch demonstrated that IKs alone was insufficient to induce DADs or to modulate repolarization heterogeneity in canine transmural ventricular tissues. However, it amplified the effects of adrenergic stimuli. At the myocyte level, we previously have shown that IKs blockade (via KCNQ1 inhibition) has minimal effects on APD and BVR under baseline conditions. During βAR stimulation and IKs blockade, BVR is significantly increased and this is, at least partly, dependent on [Ca2+]i. Here, we extend this by determining an important role for CDI of ICaL, at least in the presence of SCR. Under baseline conditions, rapidly activating delayed-rectifier K+ current (IKr) is the main repolarizing current in canine ventricular myocytes and inhibition of IKr can cause EADs attributable to APD prolongation and subsequent ICaL reactivation. During additional βAR stimulation, the balance of the repolarization reserve is altered and the role of IKr becomes more prominent; enhanced IKs prevents repolarization instability and EAD generation by other proarrhythmic mechanisms (eg, IKr inhibition or augmentation of late ICaL). In contrast, inhibition of IKs during βAR stimulation leads to APD prolongation and increased BVR and EADs, indicating that under our conditions with βAR stimulation, IKs is a major contributor to repolarization. Bárándi et al previously have shown that the degree of APD prolongation induced by pharmacological block of repolarizing currents or augmentation of depolarizing currents depends on baseline APD. Consistent with these results, we found a more pronounced APD prolongation after SCR at slow CL and in the presence of IKs blockade. In our experiments, APD prolongation after SCR is particularly pronounced because the increase in ICaL also elevates the plateau potential, which increases IKs activation and offsets the prolongation induced by ICaL (Figure 6A, bottom). This compensating mechanism is absent when IKs is inhibited. Thus, IKs inhibition exacerbates the effect of SCR on APD prolongation.
Our results provide novel mechanistic insights on the coupling between SCR, APD prolongation, and EAD occurrence, and illustrate that diastolic SCR is a central element in both TA and repolarization instability. However, the ionic mechanisms of EAD generation, particularly the relative roles of \( I_{\text{CRX}} \) and \( I_{\text{cal,Mo}} \), are complex and cannot be fully determined based on our data. Moreover, the measurement of the lag between the start of the aftercontraction and the EAD upstroke does not take into account the delay between SCR and activation of contraction or the SCR-induced slowing of repolarization in the priming phase before the EAD upstroke. This lag is likely because of differential Ca\(^{2+}\) thresholds for the activation of contraction vs the activation of membrane currents.

APD prolongation after SCR results from increased \( I_{\text{cal,Mo}} \), which enhances Ca\(^{2+}\) loading via increased sarcolemmal Ca\(^{2+}\) influx. Enhanced loading along with reduced Ca\(^{2+}\) efflux serves to restore and fine-tune SR Ca\(^{2+}\) content to maintain Ca\(^{2+}\)-induced Ca\(^{2+}\) release efficacy, as previously has been described in rat ventricular myocytes. However, during increased Ca\(^{2+}\) load, these mechanisms will readjust, promoting SCR, facilitating the occurrence of afterdepolarizations. Consistent with this, we found that the probability of observing a DAD was not significantly altered by the presence of a DAD on the previous beat. This strongly implies that under our experimental conditions, the reduction in myocyte Ca\(^{2+}\) load during a DAD is overcome by the increased sarcolemmal Ca\(^{2+}\) influx during the following prolonged AP. Thus, APD prolongation after SCR contributes to the vicious cycle of Ca\(^{2+}\) loading and, ultimately, overload. These results are in agreement with the recent modeling study by Morotti et al that established that \( I_{\text{cal,Mo}} \) predominantly inactivates because of CDR and that (strongly) reduced CDR can cause Ca\(^{2+}\) overload and DADs.

Inhibition of SCR by ryanodine and tetracaine previously has been described and the results presented here agree with those data. We extend these observations by showing a concomitant decrease in BVR. Both ryanodine and tetracaine are useful for mechanistic studies, but because of their deleterious effects in vivo they cannot be used as therapeutic agents. In contrast, both magnesium and flecainide are commonly used antiarrhythmic agents. Here, we show that both these agents can lead to a reduction in BVR and arrhythmogenic events, most likely because of stabilization of Ca\(^{2+}\) handling in the single myocyte. Similarly, we confirm the usefulness of modulating Calmodulin/CaMKII during increased Ca\(^{2+}\) loading as an antiarrhythmic strategy. CaMKII phosphorylation has been shown to induce a different gating mode (mode 2) of the \( I_{\text{cal,Mo}} \) channel, thereby reducing inactivation and favoring Ca\(^{2+}\) entry and the occurrence of EADs and DADs. Interestingly, when CAMKII inhibition is applied, a disconnect appears between SCR events and APD. Whether this is attributable to alterations in CDR or because of effects on other CAMKII substrates, such as \( I_{\text{cal,Mo}} \), is not clear and further investigation is warranted. In this regard, the development of selective CaMKII modulators suitable for antiarrhythmic interventions in humans is awaited.
Conclusions
We have shown that after SCR, inactivating $I_{\text{CaL}}$ is increased and APD and QT intervals are prolonged, most likely because of reduced Ca$^{2+}$-induced Ca$^{2+}$ release-dependent inactivation of this current. The degree of APD prolongation is exacerbated by inhibition of $I_{\text{Kr}}$. This contributes to increased BVR and...
spatial dispersion of repolarization during ISO-induced diastolic Ca\textsuperscript{2+} release and, aside from DAD-mediated TA, may be an additional mechanism contributing to arrhythmogenesis. Pharmacological interventions that regularize SCR or inhibit SCR with or without preserved systolic contractions reduce BVR. Our data provide novel insights into arrhythmogenic mechanisms during increased Ca\textsuperscript{2+} loading.

---

What Is Known?

- Beat-to-beat variability of ventricular repolarization (BVR) duration has been proposed as a more predictive marker of Torsades de Pointes (TdP) arrhythmia than repolarization duration alone. The cellular mechanisms of BVR remain to be fully elucidated.
- During intense β-adrenergic receptor stimulation, Ca$^{2+}$ load of the myocyte increases. Additional blockade of the slowly activating delayed-rectifier K+ current ($I_{Ka}$) amplifies this effect and exaggerates BVR.
- Spontaneous sarcoplasmic reticulum Ca$^{2+}$ release (SCR) during Ca$^{2+}$ overload can cause membrane depolarization via Ca$^{2+}$-dependent ion currents, resulting in afterdepolarizations and, potentially, triggered activity.

What New Information Does This Article Contribute?

- In canine left ventricular myocytes, late diastolic SCR during β-adrenergic stimulation causes prolongation of the following action potential (AP), especially during $I_{Ka}$ blockade. The irregular occurrence of SCR exaggersates BVR by interspersed AP prolongation. Pharmacological interventions that prevent or regularize SCR reduce BVR.
- By sarcoplasmic reticulum unloading, late diastolic SCR decreases systolic sarcoplasmic reticulum Ca$^{2+}$ release during the following AP. This reduces Ca$^{2+}$-dependent inactivation of the L-type Ca$^{2+}$ current, causing the AP prolongation.
- In a canine model of drug-induced long-QT1 syndrome, β-adrenergic challenges cause paradoxical repolarization prolongation, exaggerated BVR, and aftercontractions just before the initiation of TdP. QT, monophasic AP, and $T_{peak}-T_{end}$ interval of the beats after aftercontractions are significantly prolonged. The Ca$^{2+}$ antagonist verapamil prevents aftercontractions and arrhythmia.

A significant increase in BVR has been observed in animal models and selected human subjects before TdP onset. The in vivo mechanisms of this remain incompletely understood but reside partly in the cardiac myocyte. Cellular Ca$^{2+}$ overload can augment BVR and plays a major role in arrhythmogenesis. Here, we aimed at elucidating Ca$^{2+}$-dependent mechanisms of augmented BVR during β-adrenergic stimulation and $I_{Ka}$ blockade, in effect mimicking long-QT1 syndrome. We show that APs prolong significantly after SCR, leading to increased BVR if the occurrence of SCR is irregular. An intact $I_{Ka}$ prevents much of the repolarization prolongation. AP prolongation is driven by reduced Ca$^{2+}$-dependent inactivation of L-type Ca$^{2+}$ current resulting from decreased systolic sarcoplasmic reticulum Ca$^{2+}$ release after SCR. Pharmacological interventions that prevent or regularize SCR reduce BVR, which suggests novel antiarrhythmic approaches against TdP under these conditions. We also demonstrate that during β-adrenergic stimulation and $I_{Ka}$ blockade in vivo, paradoxical prolongation of repolarization and aftercontractions precede TdP, suggesting that the identified cellular mechanisms have relevance for arrhythmogenesis in the intact heart. Thus, myocardial Ca$^{2+}$ overload and delayed and early afterdepolarizations not only can cause arrhythmias via triggered activity but also by increasing temporal and spatial dispersion of repolarization, promoting reentrant excitation.

Extended Methods

Cell-isolation procedure
Adult female beagle dogs were used for the myocyte isolations. Anesthesia was induced with 45 mg/kg pentobarbital. Once full anesthesia was reached, the chest was opened via a left thoracotomy and the heart was excised and placed in an O₂-gassed Ca²⁺-free standard buffer solution at approximately 4 °C. The cell-isolation procedure was the same as previously described. Briefly the left-anterior descending coronary artery was cannulated and perfused. After ~20 min of collagenase perfusion and subsequent washout of the enzyme, the epicardial surface layer was removed from the LV wedge until a depth of ≥3 mm was reached. Softened tissue samples were collected from the midmyocardial layer underneath while contamination with the epicardium was avoided. Samples were gently agitated, filtered and washed. LV midmyocytes were stored at room temperature in standard buffer solution (vide infra) and only quiescent rod-shaped cells with clear cross-striations were used for the experiments. Cells were used within 48 h of isolation.

Sharp-electrode action potential recordings
Transmembrane action potentials (APs) were recorded at 37 °C using high-resistance (30–60 MΩ) glass microelectrodes filled with 3 mol/L KCl with a microelectrode amplifier (Axoclamp-2B, Axon Instruments, Inc). Intracellular pacing was done at various cycle lengths (CLs; 500 ms – 2000 ms). Only cells showing a stable spike-and-dome AP morphology and resting membrane potential were accepted for the experiments. Myocyte contractions were recorded with a video edge motion detector (Crescent Electronics, Sandy, UT, USA).

Ca²⁺ measurements
Isolated myocytes were loaded with the acetoxymethyl ester of indicator Fluo-3 or Fura-2 (Molecular Probes; 5 μmol/L, 5 min loading and 30 min de-esterification). Electrophysiological control for current-clamp and voltage-clamp experiments with simultaneous [Ca²⁺], measurements was achieved using the perforated patch clamp technique with amphotericin-B (240 μg/ml). The switch-clamp facility (frequency 1–3 kHz and gain 1–3) of the Axoclamp-2B voltage clamp amplifier (Axon Instruments, CA, USA) was used to overcome the access resistance of the perforated patch. All experiments were performed at 37 °C.
Drugs and experimental solutions

The standard buffer solution used for the experiments was composed of (in mmol/L): NaCl 145, KCl 4.0, CaCl$_2$ 1.8, MgCl$_2$ 1.0, glucose 11 and HEPES 10, pH 7.4 with NaOH at 37 °C. In a subset of experiments, extracellular [Mg$^{2+}$] was increased to 5 mmol/L by the addition of 4 mmol/L MgSO$_4$. In other experiments, extracellular [Ca$^{2+}$] was increased to 3.6 mmol/L to further increase cellular Ca$^{2+}$ loading.

500 nmol/L HMR1556 ((3R,4S)-(+)-N-[3-hydroxy-2,2-dimethyl-6-(4,4,4-trifluorobutoxy)chroman-4-yl]-N-methylmethanesulfonamide; a gift from Dr. H. Gögelein, Sanofi-Aventis Germany GmbH, Frankfurt, Germany) was used to selectively and completely block I$_{KS}$. Sarcoplasmic reticulum (SR) Ca$^{2+}$ release through the ryanodine receptor (RyR) was inhibited with 1 μmol/L ryanodine (RBI, Natick, MA, USA) or stabilized using 5 μmol/L tetracaine (Sigma-Aldrich Zwijndrecht, The Netherlands). Caffeine (Sigma-Aldrich Zwijndrecht, The Netherlands; maximally 500 μmol/L) was used to increase RyR open probability. Ca$^{2+}$/Calmodulin-dependent kinase (CaMKII) activity was modulated using the CaMKII inhibitor KN93 (Sigma-Aldrich Zwijndrecht, The Netherlands; 5 μmol/L) and the calmodulin inhibitor W7 (Tocris Bioscience, Bristol, UK; 1 μmol/L). The class-1C antiarrhythmic agent flecainide (MedaPharma, Amstelveen, The Netherlands) was employed in a subset of experiments. At 6 μmol/L, flecainide results in a 40% decrease in RyR activity$^5$ as well as affecting multiple other targets (40% inhibition of I$_{To}$, significant inhibition of (late) I$_{Na}$ and ~50% inhibition of HERG K$^+$ channels$^6$).

For perforated patch experiments the patch pipette solution contained (in mmol/L): KCH$_3$O$_3$S 125, KCl 20, NaCl 10, HEPES 10, MgCl$_2$ 5, K$_2$EGTA 0.1, titrated to 7.2 with KOH with patch pipette resistance being 2-3 MΩ. In voltage clamp experiments, K$^+$ currents were blocked by addition of 500 nmol/L HMR1556, 5 mmol/L 4-aminopyridine and 100 nmol/L BaCl$_2$ to the standard buffer solution. Extracellular Ca$^{2+}$ was raised (to 3.6 or 5.0 mmol/L) to further enhance cellular Ca$^{2+}$ loading.

HMR1556, ryanodine, tetracaine, caffeine, W7 and KN93 were initially dissolved in dimethyl sulfoxide (DMSO) and then diluted so that the concentration of the solvent was maximally 0.1% in the superfusate, a concentration that has no measurable effects on AP or ionic currents.
βAS was applied by 100 nmol/L isoproterenol in all experiments. This agent was originally dissolved in distilled water containing 30 μmol/L ascorbic acid and then stored in the dark at 4 °C until use.

When assessing the effect of pharmacological interventions, all conditions were kept constant for several minutes until APD and cell shortening reached steady state. Analyses were performed using these steady-state data.

Data analysis
Detection of EADs, DADs and determination of APD, BVR and DAD parameters was done in a semi-automated fashion using a custom Matlab (The Mathworks, Natick, MA, USA) script. Briefly, Axon (Axon Instruments, CA, USA) data files were loaded into Matlab. AP upstroke was detected based on peaks in the numerically calculated dV/dt, and APD₉₀ was determined. Subsequently, the diastolic interval between APD₉₀ of one beat and the point of maximum dV/dt of the next beat was processed for all beats. The signal was low-pass filtered at 30 Hz to reduce noise. All peaks in the filtered signal were determined and resting membrane potential was defined as the average value between the smallest (most negative) local maximum and local minimum. The amplitude of all other peaks was determined relative to this resting membrane potential. DADs were identified as a local maximum in the filtered signal of more than 2 mV in amplitude and manually confirmed by the investigators. EADs were detected as positive local maxima in the low-pass filtered dV/dt signal preceded and followed by negative local minima. Detection of EADs was manually validated.

BVR was determined using a sliding window of 30 consecutive beats using: \[ \text{BVR} = \frac{\sum |\text{APD}_{i+1} - \text{APD}_{i}|}{n_{\text{beats}} \times \sqrt{2}} \], and mean BVR for a given condition (CL and/or pharmacological intervention) was determined for each cell.

In-vivo dog model of LQT1
TdP arrhythmias were induced in an in-vivo dog model of long-QT1 syndrome as previously described. Briefly, general anesthesia was induced in 10 beagle dogs by lofentanil (0.075 mg/kg body weight i.v.), scopolamine (0.015 mg/kg), succinylcholine (1.0 mg/kg), hourly slow injections of fentanyl (0.025 mg/kg i.v.), and continuous infusion of etomidate (1.5 mg/kg/hour). Dogs were ventilated with 30% oxygen in pressurized air to normocapnia. The body temperature was kept at 37 °C with a heated water mattress. ECG standard lead II was
continuously recorded and the QT interval (QT; ms) measured from the onset of the QRS to the final end of the T wave. Left ventricular (LV) intracavitary pressures were recorded with high-fidelity catheter-tip micromanometers (Gaeltec Ltd, Dunvegan, UK and Millar Instruments Inc, Houston, TX). Under fluoroscopic guidance a MAP catheter (Boston Scientific-EP Technologies, San Jose, CA) was placed at the endocardium of the LV and RV, near the apical septum.

HMR1556 (dissolved in 20% HP-β-cyclodextrin) was infused i.v. in the dogs, initially at a rate of 0.025 mg/kg/min for 30 min and followed (if necessary) by infusions at 0.05 mg/kg/min and 0.1 mg/kg/min. At regular time intervals, boluses of isoproterenol (1.25, 2.5 or 5 μg/kg) were injected to induce torsades de pointes and in prevention experiments verapamil (0.4 mg/kg) was infused pre-isoproterenol challenge after confirming TdP inducibility with HMR1556 + ISO in the same animal. External electrical cardioversion was applied to terminate sustained TdP or its deterioration into ventricular fibrillation, if induced by isoproterenol.

**Computational modeling**

A recent model of the canine ventricular myocyte electrophysiology including βAR stimulation was extended to induce diastolic SR Ca\(^{2+}\) release in a controlled fashion, similar to a recent approach by Xie et al. Both timing (start, duration) and amplitude of diastolic SR Ca\(^{2+}\) release could be controlled.

In particular, the model was divided into two identical domains (Online Figure I) coupled by Ca\(^{2+}\) diffusion between cytosol and network SR to simulate the local origin of SCR. Diffusion time constants were based on the local control model by Restrepo et al. and diffusion was significantly slower in SR compared to cytosol, consistent with experimental observations. The late component of \(I_{\text{NaL}}\) was increased in the model to simulate the midmyocardial origin of the myocytes used in our experiments, consistent with experimental data from Zygmunt et al.

Model APD rate dependence at baseline, in the presence of ISO and in the presence of ISO+HMR1556 (simulated as 100% inhibition of \(I_{\text{Ks}}\)) was consistent with experimental data (Online Figure IIA). Parameters of the L-type Ca\(^{2+}\) current \(I_{\text{CaL}}\) were adjusted based on the experiments in the presence of ryanodine to obtain quantitative agreement on the amount of APD prolongation in the absence of SR Ca\(^{2+}\) release.

To initiate SCR, steady-state RyR activation was set to a constant value in one of the two domains for the interval of diastolic SR Ca\(^{2+}\) release such that the desired reduction in local JSR
Ca\(^{2+}\) was achieved. When steady-state RyR activation was set to 0.375 (\(SCR_{level} = 0.375\)) from \(t = 925\) ms until \(t = 950\) ms (at CL = 1000 ms), the SCR-induced prolongation of APD was consistent with experimental observations (Online Figure IIIB).

The model was paced to steady state (2000 seconds of pacing) in the presence of βAR stimulation with or without \(I_{Ks}\) inhibition, to mimic experimental conditions. The effect of diastolic SR Ca\(^{2+}\) release was examined by determining APD of a single beat at steady-state as a function of the timing and amplitude of the preceding diastolic Ca\(^{2+}\) release. In some simulations other currents / fluxes (\(I_{CaL}, I_{NaCa}, I_{Cl(Ca)}, J_{rel}\)) were blocked for the duration of this final beat.

One-dimensional strand simulations were performed as previously described.\(^{15}\) Steady-state conditions of single-cell simulations in the presence of ISO and \(I_{Ks}\) blockade were used as initial conditions for the homogeneous strand of 128 cells. The strand was subsequently paced by direct stimulation of the first 3 cells (-80 pA/pF for 2.0 ms) for 100 seconds to achieve steady-state conditions for the strand. The effect of diastolic SR Ca\(^{2+}\) release was determined by applying the methodology described above to \(k\) cells in the middle of the strand. SR Ca\(^{2+}\) release was initiated simultaneously in all \(k\) cells. The exact mechanisms by which SCR synchronizes across a sufficient number of myocytes to generate ventricular ectopic beats remain incompletely understood. Recent research by Wasserstrom et al. has suggested that an intrinsic synchronization occurs due to a decrease in variability of SCR events with increasing Ca\(^{2+}\) load.\(^{16, 17}\) Furthermore, Myles et al. have shown that localized βAR can produce spatiotemporal synchronization of SR Ca\(^{2+}\) overload and release, which can produce focal activity and arrhythmia in normal rabbit hearts.\(^{18}\) Although direct diffusion of Ca\(^{2+}\) between cells through gap junctions could further contribute to the synchronization of SCR,\(^{19}\) this was not implemented in the current model because the main goal of the present research was to determine the electrophysiological consequences of SCR, independent of the synchronization method.

A similar approach was used to study the effect of diastolic SR Ca\(^{2+}\) release on homogeneous two-dimensional sheets of virtual ‘tissue’. The tissue size was 2 x 2 cm and was simulated using 200 x 200 grid points, in line with previous studies.\(^{20, 21}\) Steady-state conditions of single-cell simulations in the presence of ISO and \(I_{Ks}\) blockade were used as initial conditions and 5 beats were simulated following stimulation of the left-most column of 200 cells (-80 pA/pF for 2.0 ms),
resulting in a planar wave activating the entire sheet. Conduction velocity was 49 cm/s. Diastolic SR Ca$^{2+}$ release was initiated simultaneously in 25% of the 40,000 cells surrounding the center of the tissues (i.e., cells with x and y coordinates between 50 and 150).

**Alterations in model equations compared to Heijman et al.$^{10}$:**

The superscript symbol $x$, is used to designate one of the two identical Ca$^{2+}$ domains. Whole-cell concentrations / currents are defined as the average of both domains and are indicated without superscript $x$.

**Altered $I_{NaL}$:**

$I_{NaL}^{NP} = 1.6 \cdot 6.500 \cdot 10^{-3} \cdot (m_L)^3 \cdot h_L \cdot (V_m - E_{Na})$

$I_{NaL}^{P,CaMK} = 1.6 \cdot 1.600 \cdot 10^{-2} \cdot (m_L)^3 \cdot h_L \cdot (V_m - E_{Na})$

**Altered $I_{CaL}$:**

$I_{V,\infty}^P = \frac{1}{70.0 \cdot (1 + \exp((V_m + 49.10)/10.349)) + 75 \cdot (1 + \exp(-(V_m + 0.213)/10.807))}$

$I_{V,\infty}^P = \frac{1}{1.02} \cdot \left(0.02 + \frac{1}{1 + \exp((V_m + 29.979)/3.1775)} \right)$

$I_{S_{V,\infty}}^P = \frac{1}{1.0004} \cdot \left(0.0004 + \frac{1}{1 + \exp((V_m + 29.979)/3.1775)} \right)$

**Altered RyR:**

$h_R = 10$

$I_{Rel,\infty}^{NP} = \frac{\alpha_{Rel}}{1 + \left(\frac{K_{Rel,\infty}[Ca^{2+}]_{SR}^{x}}{[Ca^{2+}]_{SR}^{x}}\right)^{h_R}} \cdot \frac{I_{CaL}^x}{1 + \exp\left(I_{CaL}^x + 1.5\right)} - SCR_{level}$

$I_{Rel,\infty}^{P} = 1.9925 \cdot \frac{\alpha_{Rel}}{1 + \left(\frac{K_{Rel,\infty}[Ca^{2+}]_{SR}^{x}}{[Ca^{2+}]_{SR}^{x}}\right)^{h_R}} \cdot \frac{I_{CaL}^x}{1 + \exp\left(I_{CaL}^x + 1.5\right)} - SCR_{level}$

**Altered Ca$^{2+}$ diffusion:**
\[
\begin{align*}
I_{tr}^x &= \frac{[Ca^{2+}]_{NSR}^x - [Ca^{2+}]_{JSR}^x}{\tau_{tr}}, \quad \tau_{tr} = 100 \text{ ms} \\
I_{\text{Diff, cyt}}^x &= \frac{[Ca^{2+}]_{y}^x - [Ca^{2+}]_{i}^x}{\tau_{\text{Diff, cyt}}}, \quad \tau_{\text{Diff, cyt}} = 1.00 \text{ ms}, \quad y: \text{other Ca}^{2+} \text{ domain} \\
I_{\text{Diff, ner}}^x &= \frac{[Ca^{2+}]_{NSR}^x - [Ca^{2+}]_{NSR}^x}{\tau_{\text{Diff, ner}}}, \quad \tau_{\text{Diff, ner}} = 25.0 \text{ ms}, \quad y: \text{other Ca}^{2+} \text{ domain} \\
\frac{d[Ca^{2+}]_{i,t}^x}{dt} &= -\left(\frac{(I_{Ca,b}^x + I_{pCa}^x - 2 \cdot I_{NaCa,i}^x) \cdot C_{cap} \cdot A_{cap}}{z_{Ca} \cdot F \cdot V_{myo}} + I_{up}^x \cdot \frac{V_{nsc}}{V_{myo}} - I_{\text{Diff, cyt}}^x \cdot \frac{V_{SS,SR}}{V_{myo}} - I_{\text{Diff, ner}}^x \right) \\
\frac{d[Ca^{2+}]_{NSR}^x}{dt} &= I_{up}^x - I_{tr}^x \cdot \frac{V_{SR}}{V_{NSR}} + I_{\text{Diff, ner}}^x
\end{align*}
\]
Supplemental Figures

Online Figure I. Schematic overview of the computational model of the canine ventricular myocyte. Adapted from Heijman et al.10 The model was divided into two identical domains to simulate the local origin of SCR. Only components on the left side of the model are labeled for clarity, identical components are located on the right side. The domains are coupled via diffusion of Ca$^{2+}$ (I$_{\text{diff, cyt}}$ and I$_{\text{diff, nsr}}$). All other abbreviations are as previously described.10
Online Figure II. Validation of model properties. 

A. Steady-state APD-rate dependence under baseline conditions (left panel), in the presence of ISO (middle panel) or in the presence of ISO + HMR1556 (right panel) for APs without prior DAD. Average APD for each cell is shown in blue. Average APD over all myocytes is indicated with symbols. Model APD is shown in black. Model APD-rate dependence falls within experimental range and is close to the experimental average for all conditions and CLs.

B. APD_{90} prolongation after DAD. Average APD difference between APs preceded by a DAD and those without prior DAD in the presence of ISO or ISO + HMR1556. Average APD difference for each cell is shown in blue. Average group data is indicated with symbols. Model APD prolongation after SCR is indicated with grey bars. Model APD prolongation is consistent with experimental observations.
Online Figure III. Rate-dependent characteristics of DADs in the presence of ISO (left panels) or ISO + HMR1556 (right panels). A. Percentage of cells which showed DADs during βARS. Number of cells and number of dogs are indicated in each bar. B. Average percentage of APs which had a DAD. C. Coupling interval between end of repolarization (APD_{90}) and subsequent DAD for those beats which showed a DAD. D. Average DAD amplitude. * indicates P<0.05 based on one-way ANOVA with Tukey-Kramer post-hoc test. DADs occur earlier and are larger at faster rates. Data are consistent with those of Prior and Corr\textsuperscript{22} in canine ventricular myocytes measured using a pace-pause protocol.
**Online Figure IV.** Effect of increased [Ca\(^{2+}\)]\(_o\) on APD\(_{90}\) (top panels), DAD occurrence (middle panels), and BVR (bottom panels) under baseline conditions, HMR1556 + ISO, HMR1556 + ISO + Intervention or HMR1556 + ISO + Intervention + 3.6 mmol/L [Ca\(^{2+}\)]\(_o\). **A.** Ryanodine. **B.** Tetracaine. **C.** W7. * indicates P<0.05. Only significance of intervention versus intervention in the presence of high [Ca\(^{2+}\)]\(_o\) is indicated for clarity reasons. Inset in lower-right panel shows APD\(_{90}\) in the presence of HMR1556 + ISO + W7 + increased [Ca\(^{2+}\)]\(_o\) for beats in the absence or presence of a preceding DAD.
Online Figure V. Multicellular simulations in a one-dimensional strand of 128 cells in the presence of ISO and I_{ks} blockade. A. APs during steady-state pacing at CL = 1000 ms (top panel). Prior to beat (0), diastolic SR Ca^{2+} release was initiated in cells 32-96 (arrow). The bottom panel shows an overlay of Vm for cell 10 (orange, no DAD), cell 64 (grey, with DAD indicated by arrow) and cell 118 (green, no DAD) for these three beats. B. APD_{90} for all cells in the strand for these 3 beats. Cells 10, 64 and 118 have been indicated by vertical dashed lines. The presence of a preceding ‘spontaneous’ diastolic SR Ca^{2+} release (SCR) causes a pronounced prolongation of APD_{90} of beat (0) throughout the strand (black line). In addition, an
increase in the spatial dispersion of repolarization could be observed. C. Average repolarization time (activation time + APD\(_{90}\); left panel) and spatial dispersion of repolarization (maximum repolarization time – minimum repolarization time; right panel) as a function of the number of cells with SCR. SCR caused a progressive increase in the average repolarization time. Dispersion of repolarization was influenced by the number of cells with SCR (with a maximum around 50\%). A low spatial dispersion of repolarization was expected at 100\%, when all cells exhibit SCR. However, spatial dispersion of repolarization also depends on the timing of the SCR. Since SCR was initiated at the same time in all cells, but the time of Ca\(^{2+}\)-induced Ca\(^{2+}\)-release differs due to AP propagation along the strand, there is a longer time for SR refilling after the SCR in cell 128 than in cell 1. As such, the amount of APD prolongation differs throughout the strand resulting in an increased spatial dispersion even at 100\%. Spatial dispersion of repolarization is a complex, non-monotonic function that depends on the number of cells with SCR, their location in the strand, the timing of the SCR and the conduction velocity.
Online Figure VI. Multicellular simulations in homogeneous two-dimensional tissue of 200x200 nodes in the presence of ISO and I_{Ks} blockade. A. APs (top panel) and [Ca^{2+}]_i (bottom panel) for 5 beats during steady-state pacing at 1000-ms CL for a cell on the edge of the tissue (at coordinates (4,4), black lines) and a cell in the center of the tissue (blue lines). The location of these cells is indicated with stars in panels B and C (left). APD_{90} of each AP is given below each beat in the corresponding color. Diastolic SR Ca^{2+} release was induced from 1925 to 1950 ms (indicated by arrows) for a region of 100x100 cells (25% of the cells) around the center of the tissue (i.e., cells with x and y coordinates between 50 and 150, dashed box in panels B and C). B. Spatial electrophysiological properties of beat 2. The left panel shows repolarization time (activation time + APD_{90}) at every point in the tissue. Average repolarization time was 291 ms and spatial dispersion of repolarization (maximum-minimum repolarization time) was 29 ms. The
eight smaller panels on the right show voltage maps at different time instants. The voltage maps show a homogeneous diastolic interval followed by a planar wave propagating from left to right following pacing (conduction velocity of 49 cm/s). Repolarization occurs uniformly around 1290 ms. C. Similar to panel B for beat 3 which is preceded by diastolic Ca\(^{2+}\) release in a subset of the cells. Average repolarization time is longer (305 ms) and shows increased spatial dispersion (45 ms), in line with one-dimensional simulations and in-vivo experimental data. Voltage maps identify the DAD in the center of the tissue and the prolonged repolarization of this same area during the following beat.
Online Figure VII. Multicellular simulations in homogeneous two-dimensional tissue of 200x200 nodes in the presence of ISO and I_{Ks} blockade after inhibition of Ca^{2+}-dependent inactivation (CDI) of I_{CaL}. Simulation protocol and figure layout are identical to Online Figure VI, except for the inhibition of CDI for these 5 beats (after pacing to steady-state in the presence of ISO and I_{Ks} blockade). Inhibiting CDI prolongs APD_{90}, consistent with experimental data and single-cell simulations (Figure 6). Inhibition of CDI prevents APD prolongation following diastolic SR Ca^{2+} release despite similar DAD and systolic Ca^{2+} transient properties and prevents increased spatial dispersion of repolarization. Note that due to this APD prolongation different time-points were used for the voltage maps in panels B and C (indicated in purple).
Online Figure VIII. ECG, left-ventricular (LV) monophasic action potential (MAP) and LV pressure (LVP) recordings following a bolus of ISO during continuous HMR1556 infusion in the absence (panel A) or presence (panel B) of verapamil (0.4 mg/kg) in the same dog. RR intervals are indicated above the ECG traces and QT and LV MAP durations are indicated below the ECG and LV MAP signals, respectively. TdP was induced in the absence of verapamil and was preceded by aftercontractions in the LVP signal (indicated by arrows). Verapamil reduced the systolic LVP by approximately 17% and prevented the aftercontraction formation and TdP induction.
