Obesity and its associated cardiovascular, metabolic, and renal disorders have rapidly become a major threat to global health. Worldwide obesity has nearly doubled since 1980 and current estimates indicate that >1.4 billion adults are overweight or obese.1 In the United States, >65% of adults are overweight and 36% are obese with a body mass index.
Several other countries report even higher rates of obesity. For example, the estimated prevalence of obesity in adults exceeded 50% for men in Tonga and for women in Kuwait, Kiribati, Federated States of Micronesia, Libya, Qatar, Tonga, and Samoa. Other countries report even higher rates of obesity. For example, the estimated prevalence of obesity in adults exceeded 50% for men in Tonga and for women in Kuwait, Kiribati, Federated States of Micronesia, Libya, Qatar, Tonga, and Samoa.

Major consequences of being overweight or obese include higher prevalence of hypertension and a cascade of associated cardiorenal and metabolic disorders. Studies in diverse populations throughout the world have shown that the relationship between BMI and systolic and diastolic blood pressure (BP) is nearly linear. Risk estimates from the Framingham Heart Study, for example, suggest that 78% of primary (essential) hypertension in men and 65% in women can be ascribed to excess weight gain. Clinical studies indicate that maintenance of a BMI <25 kg/m² is effective in primary prevention of hypertension and that weight loss reduces BP in most hypertensive subjects.

Despite impressive evidence indicating a major role for excessive weight gain in raising BP, not all obese persons are hypertensive. It is clear, however, that excess weight gain shifts the BP frequency distribution toward higher levels increasing the probability that a person’s BP will register in the hypertensive range (Figure 1). Thus, some obese people will have BPs lower than 140/90 mm Hg, the level usually used to indicate hypertension. However, even those who are classified as obese normotensives have higher BP than they would at a lower body weight and weight loss lowers BP in normotensive and hypertensive obese subjects. As discussed later, the effect of obesity on BP may also depend on how long a person has been overweight, worsening as excess adiposity is maintained during several years.

The distribution of fat is another important consideration. Most population studies that have investigated the relationship between obesity and BP have measured BMI rather than visceral or retroperitoneal fat, which seems to be better predictors of increased BP than subcutaneous fat. Although the importance of obesity, especially when associated with increased visceral or retroperitoneal fat, is well established as a cause of hypertension, the pathophysiological mechanisms involved are complex and have not been fully elucidated. In this review, we focus mainly on those factors that initiate obesity-induced increases in BP by impairing renal-pressure natriuresis, leading to development of diabetes mellitus, dyslipidemia, and target organ injury, including chronic kidney disease (CKD). Some of these issues have been considered in previous reviews; therefore, our discussion of obesity’s impact on CKD is brief and intended mainly to illustrate how this may gradually exacerbate hypertension and make it more difficult to control. In fact, BP seems to be more difficult to control in obese patients and obesity is recognized to be a common cause of treatment-resistant hypertension.

**Hemodynamic and Renal Changes in Obesity-Induced Hypertension**

Studies in experimental animals have provided mechanistic insights into the cardiovascular and renal changes associated with obesity. A highly reproducible rise in BP is observed with excess weight gain induced by a high-fat diet in dogs and rabbits. The metabolic, endocrine, cardiovascular, and renal changes caused by dietary-induced obesity in these experimental animals closely mimic the changes observed in obese humans (Table). Some of these changes occur rapidly during overfeeding and later become obscured by pathological changes. For example, glomerular hyperfiltration early in obesity may be replaced by a gradual decline in glomerular filtration rate because renal injury and nephron loss occur in association with prolonged hypertension, diabetes mellitus,
and dyslipidemia. Some of the same changes occur in obese rodents, although systemic hemodynamics and renal changes are not as well documented in many cases. Also, many commonly used rodent models of genetic obesity have disruption of central nervous system (CNS) signaling pathways that link obesity with sympathetic nervous system (SNS) activation and hypertension. Therefore, some rodent models of obesity, such as those with melanocortin 4 receptor (MC4R) or leptin gene mutations, have normal or reduced SNS activity and decreased BP, despite inflammation, insulin resistance, dyslipidemia, and other metabolic changes associated with obesity.

GFR indicates glomerular filtration rate; and \( \dot{V}O_{2} \), total body oxygen consumption.

*The GFR and renal blood flow refer to the early phases of obesity before major loss of nephron function has occurred.

†In some instance, sympathetic activity is inferred from indirect measurements, such as tissue norepinephrine spillover or from denervation studies; plasma insulin and leptin concentrations refer to fasting levels.

**Obesity Increases Tissue Blood Flow and Cardiac Output, and Decreases Blood Flow Reserve**

Obesity is associated with extracellular fluid volume expansion and increased blood flow in many tissues which, in turn, increases venous return and cardiac output. Cardiac output increases in parallel with increased body weight and part of this increase is because of blood flow that supplies the extra adipose tissue. However, blood flow is increased in other tissues, including the heart, kidneys, gastrointestinal tract, and skeletal muscles. Some of the extra blood flow is because of growth of tissues and organs in response to increased workload and metabolic demands associated with obesity. However, blood flows of tissues such as the kidneys, skeletal muscle, and heart are increased in obese subjects even when flow is expressed per gram tissue weight. Thus, obesity is associated with functional vasodilation that is probably because of increased metabolic rate and higher tissue oxygen consumption.

Despite higher resting tissue blood flow, there is reduced blood flow reserve, which limits the rise in blood flow that normally occurs in exercise. This decreased blood flow reserve may be due, in part, to endothelial dysfunction and weight reduction often improves flow-mediated vasodilation in obese individuals. Accelerated arterial stiffening occurs in elderly, middle-aged, young adults (aged 20–40 years) and even in children who are obese. Moreover, higher aortic pulse-wave velocity, a measure of aortic stiffness, strongly correlates with increases in BMI, waist circumference and waist:hip ratio independent of systolic BP, race, and sex.

The mechanisms responsible for the deleterious effects of obesity on the vasculature have not been fully elucidated, but are probably because of interactions of multiple disorders, including increased BP, inflammation, hyperglycemia, lipotoxicity caused by non-\( \beta \)-oxidative metabolism of fatty acids, and...
acids, oxidative stress, and activation of multiple neurohumoral systems. There is evidence that excess visceral fat is an important source of cytokines and other factors that create a milieu of oxidative stress and inflammation that contributes to endothelial dysfunction, vascular stiffening, and eventually atherosclerosis.20

**Obesity Impairs Renal-Pressure Natriuresis**

Increased renal sodium reabsorption plays a major role in initiating the rise in BP associated with excess weight gain and obese subjects require higher than normal BP to maintain sodium balance, indicating impaired renal-pressure natriuresis.21 At least 3 major factors seem to impair renal-pressure natriuresis and increase BP during rapid, excessive weight gain (Figure 2): (1) physical compression of the kidneys because of increased visceral, retroperitoneal, and renal sinus fat; (2) renin–angiotensin–aldosterone system (RAAS) activation, including activation of mineralocorticoid receptors (MRs) independent of aldosterone; and (3) SNS activation, especially increased renal sympathetic nerve activity (RSNA). Also, CKD may, over a much longer time, amplify the BP effects of these mechanisms, making obesity-associated hypertension more difficult to control and less easily reversed by weight loss.

**Possible Role of Natriuretic Peptide Deficiency in Obesity Hypertension**

Although this review focuses mainly on the role of physical compression of the kidneys and activation of the RAAS and SNS in obesity hypertension, a relative deficiency of natriuretic peptides has also been suggested to contribute to impaired renal-pressure natriuresis.24 Therefore, dysfunction of the natriuretic peptide system may also contribute to impaired salt and water homeostasis in obesity hypertension. Cardiac-derived natriuretic peptides may also play a role in metabolic regulation. Genetically engineered mice that lack natriuretic peptide receptor-C (NPR-C) to promote clearance of atrial natriuretic peptide and B-type natriuretic peptide have increased circulating levels of these peptides, browning of white adipocytes, and increased thermogenesis compared with wild-type mice.25 Thus, high levels of natriuretic peptides could exacerbate obesity-induced metabolic abnormalities. However, the importance of abnormal secretion and clearance of natriuretic peptides in contributing to obesity hypertension and associated metabolic abnormalities is still unclear and has been considered more extensively in other reviews.24,26

**Renal Compression Caused by Visceral, Retroperitoneal, and Renal Sinus Fat**

Increased visceral and retroperitoneal fat may increase BP by physically compressing the kidneys. Excess fat accumulation in and around the kidneys is associated with increased intrarenal pressures, impaired pressure natriuresis, and hypertension.12 In patients with visceral obesity, intra-abdominal pressure rises in proportion to sagittal abdominal diameter, reaching levels as high as 35 to 40 mmHg.27 These high pressures compress the renal veins, lymph vessels, ureters, and renal parenchyma. Also, in obese dogs, rabbits and humans, retroperitoneal fat often encapsulates the kidney, adheres tightly to the renal capsule, and invades the renal sinuses, causing additional compression and increased intrarenal pressures (Figure 3).10,12 In obese rabbits fed a high-fat diet, increased renal sinus fat was associated with distortion and prolapse of the renal medullary ducts of Bellini, which would tend to restrict urinary outflow.28,29

In obese humans increases in retroperitoneal and renal sinus fat are associated with hypertension. Chandra et al.10 found in a large cohort of the Dallas Heart Study that visceral obesity and especially retroperitoneal fat were uniquely correlated with incident hypertension. Chughtai et al.11 reported that renal sinus fat was associated with stage II hypertension and the number of antihypertensive medications required to control BP. In the Framingham Heart Study, individuals with fatty kidneys (high-perinephric fat levels) had >2-fold higher risk for hypertension, which persisted after adjustment for BMI and visceral fat.22 Fatty kidneys were also associated with increased risk for CKD after adjustment for BMI and visceral adiposity.

In addition to compressing the kidneys, retroperitoneal and renal sinus fat may cause inflammation and expansion of renal medullary extracellular matrix that could further impair renal function. Glycosaminoglycan content and tissue concentration of hyaluronan, important components of renal medullary extracellular matrix, are markedly elevated in the renal medulla of obese dogs and rabbits compared with lean controls.29,33 Although the stimulus for increased hyaluronan in renal medulla is uncertain, its accumulation is associated with increased interstitial fluid pressure, tissue edema, and inflammation in other conditions besides obesity.
Supporting the concept that visceral obesity compresses the kidneys is the observation that renal interstitial fluid hydrostatic pressure was elevated to 19 mm Hg in obese dogs compared with only 9 to 10 mm Hg in lean dogs. Although small increases in renal interstitial fluid pressure inhibit renal tubular reabsorption, large increases of the magnitude found in obese dogs would compress the thin loops of Henle and vasa recta, reducing renal tubule flow and medullary blood flow, and increasing fractional NaCl reabsorption in the loops of Henle.

Increased sodium reabsorption caused by renal compression could indirectly contribute to renal vasodilation, glomerular hyperfiltration, and increased renin secretion in obese subjects. Increased loop of Henle reabsorption would reduce macula densa NaCl delivery and cause, via tubuloglomerular feedback, reductions in afferent arteriolar resistance and increases in renal blood flow, glomerular filtration rate, and renin secretion. Glomerular hyperfiltration and elevated BP would tend to return macula densa NaCl delivery toward normal, despite increased loop of Henle reabsorption, helping to restore sodium balance. Although renal compression cannot account for the initial rise in BP during rapid weight gain, they may, partly, explain why visceral obesity and increased renal fat are more closely associated with hypertension than subcutaneous fat.

Accumulation of fat in and around the kidneys may have additional lipotoxic effects on the kidneys. Lipid accumulation in key organs (ectopic fat storage) seems to impair organ function because of increased oxidative stress, mitochondrial dysfunction, and endoplasmic reticulum stress.

In contrast to multiple studies in dogs, rabbits, and humans suggesting that kidney compression contributes to obesity hypertension, this does not seem to be a major factor in rodents. Even in morbidly obese rodents (eg, ob/ob mice), there is little adherence of fat to the kidney capsule or evidence of renal compression. In fact, kidneys from obese rats and mice seem to be floating in the surrounding fat with minimal invasion of the fat into the capsule or renal sinuses (Figure 3). However, the mechanisms responsible for the relative protection from adherence and invasion of fat into the kidneys of rodents, compared with humans and dogs, are unknown and a potentially interesting area for further research.

Thus to date, the only proven strategies to reduce visceral, retropertioneal, and renal sinus fat and their adverse effects on cardiovascular, metabolic, and renal function are bariatric surgery for severely obese patients and lifestyle modification with dietary changes and increased physical activity. A small, randomized controlled trial, in which a small amount of visceral fat (0.8% of total body fat) was removed by omentectomy in patients who underwent gastric banding demonstrated improvements in glucose regulation, compared with those who only received gastric-banding treatment. Improved glucose tolerance, increased insulin sensitivity, and decreased fasting glucose occurred in the absence of significant effects of omentectomy on body weight, although effects on BP and kidney function were not reported; further longitudinal studies are needed to determine the effect on ectopic fat depots in and around the kidneys on BP and renal function.

**RAAS Activation in Obesity**

The importance of the RAAS in obesity hypertension has been previously reviewed and will, therefore, be considered briefly. Obese subjects, especially those with visceral obesity, often have mild-to-moderate increases in plasma renin activity, angiotensinogen, angiotensin-converting enzyme (ACE) activity, angiotensin II (Ang II, and aldosterone. RAAS activation occurs despite NaCl retention, volume expansion, and hypertension, which typically suppress renin secretion and Ang II formation.

Multiple mechanisms activate the RAAS activation in obesity, including compression of the kidneys and increased SNS activation. Some studies also suggest a role for a local RAAS in adipose tissue. Although angiotensinogen is produced in adipocytes, the importance of adipose tissue as a source of Ang II formation is still unclear. There have been no studies, to our knowledge, directly demonstrating that adipocyte-specific-derived angiotensinogen or Ang II have a major influence on BP regulation in obesity. Ang II has also been suggested to play a role in adipocyte growth and differentiation in rodents but there is little evidence in humans that inhibitors of the RAAS have major effects on adiposity or body weight.
Role of Ang II in Obesity Hypertension

An important role for Ang II in stimulating renal NaCl reabsorption and in mediating obesity hypertension is supported by studies in experimental animals demonstrating that Ang II receptor blockade or ACE inhibition attenuates sodium retention, volume expansion, and increased BP in obesity. In obese Zucker rats, there is increased sensitivity to the BP effects of Ang II and RAAS blockade lowers BP to a greater extent than in lean rats, despite lower plasma renin activity. Although smaller clinical trials have clearly shown that angiotensin receptor blockers, renin inhibitors, or ACE inhibitors are effective in lowering BP in obese hypertensive patients, there have been no large-scale clinical studies comparing the effectiveness of RAAS blockers in obese and lean hypertensive patients.

Activation of the RAAS may contribute to glomerular injury and nephron loss associated with obesity not only by increasing BP but also through intrarenal effects. For example, constriction of efferent arterioles by Ang II exacerbates the rise in glomerular hydrostatic pressure caused by arterial hypertension. Studies in obese type II diabetic patients indicate that ACE inhibitors or angiotensin receptor blockers slow progression of CKD. However, further studies are needed in nondiabetic, obese subjects to determine the efficacy of RAAS blockers compared with other antihypertensive agents, in treating hypertension and reducing the risk of renal injury.

Role of MR Activation in Obesity Hypertension

Antagonism of MR also provides an important therapeutic tool for lowering BP and attenuating target organ injury in obesity hypertension. In obese dogs, for example, MR antagonism markedly attenuated sodium retention, hypertension, and glomerular hyperfiltration (Figure 4). The observation that MR antagonism attenuated glomerular hyperfiltration may also have important implications for renal protection, although there are no studies, to our knowledge, that have directly tested this in obese humans.

Administration of MR antagonists provides significant antihypertensive benefit in treatment-resistant obese patients, although there was no correlation between plasma aldosterone levels and BP responses to MR blockade. BP reductions after MR antagonism in obese patients with resistant hypertension occurred despite concurrent therapy with ACE inhibitors or angiotensin receptor blockers, suggesting that MR activation in obesity can occur independently of Ang II–mediated stimulation of aldosterone secretion.

It is not clear, however, why MR blockade is so effective in lowering BP and altering renal function in obesity, despite only mild increases, or even slight decreases in plasma aldosterone, especially in those treated with ACE inhibitors or angiotensin receptor blockers. One explanation is that obesity enhances sensitivity to aldosterone-mediated MR activation. Although obese Zucker rats have increased abundance of the α subunit of epithelial sodium channel in the renal cortex, it is unclear whether there is increased expression of the other subunits necessary to form functional epithelial sodium channels or whether these changes play a major role in obesity hypertension.

Obesity also increases renal tubular epithelial cell expression of Rac1, a small guanosine triphosphate–binding protein member of the Rho family of guanosine triphosphatases that activates MR signal transduction. Several metabolic factors associated with obesity, including hyperglycemia, induce renal Rac1 activation and Rac1 inhibitors attenuate proteinuria and renal injury in obese hypertensive animals.

Glucocorticoids may also contribute to MR activation in obesity. Although cortisol can bind to MR with high affinity, renal epithelial cells are normally protected by the enzyme 11β-hydroxysteroid dehydrogenase type 2, which converts cortisol to cortisone, a glucocorticoid that does not avidly bind MR. We found that 11β-hydroxysteroid dehydrogenase type 2 is markedly downregulated in kidneys of obese dogs, providing a potential mechanism, by which cortisol might activate...
the MR. Also, the ability of cortisol to activate MR may be influenced by the intracellular redox state, with increased oxidative stress resulting in increased MR activation by cortisol. However, the importance of these mechanisms is still unclear and further studies are needed to determine why MR blockade is so effective in lowering BP in obesity hypertension.

**Autonomic Nervous System and Renal Nerves in Obesity**

*Decreased Cardiac Parasympathetic Activity in Obesity*

Obesity generally decreases parasympathetic tone and increases sympathetic activity. These changes in autonomic activity are associated with increased heart rate (HR), decreased HR variability, and reduced baroreflex sensitivity, as well as hypertension.17,57,58 The elevated HR in obese humans and obese dogs is mainly because of decreased parasympathetic tone rather than increased sympathetic activity.57,59 Conversely, weight reduction increases parasympathetic tone and HR variability while decreasing HR.60 Although obesity increases sympathetic activity in many tissues, including the kidneys and skeletal muscles, cardiac sympathetic activity, as assessed by the norepinephrine spillover method, may be normal or reduced because of baroreflex inhibition of cardiac SNS activity.61

**SNS Activation in Obesity**

Multiple lines of evidence indicate that increased SNS activity contributes to obesity hypertension5,12: (1) SNS activity, assessed by direct recordings of muscle sympathetic nerve activity (MSNA) or norepinephrine spillover, is increased in some, but not all, tissues of obese hypertensive subjects; (2) administration of α/β-adrenergic blockers or clonidine, which attenuates sodium retention and hypertension in obese animals and obese patients with resistant hypertension. Although excessive caloric intake and weight gain clearly increase SNS activity and BP, SNS overactivity, via ensuing downregulation of β-adrenergic responsiveness, has also been suggested to exacerbate weight gain in some hypertensive patients.61

**Obesity Causes Mild SNS Activation That is Differentially Controlled in Various Tissues and Depends on Body Fat Distribution**

Although cardiac SNS activity may not be elevated, RSNA and MSNA are generally increased in obese compared with lean subjects. In rabbits, for example, RSNA increases within 1 week after starting a high-fat diet while baroreflex control of RSNA is attenuated.14 Obesity-induced increases in SNS activity are usually mild and not sufficient to reduce tissue blood flow. In fact, obesity is often associated with increased blood flow in the kidneys and many other tissues. However, increased RSNA stimulates renin secretion and renal sodium reabsorption which, in turn, contribute to development and maintenance of obesity hypertension.5,12

Ethnicity and other factors, such as fat distribution influence SNS responses to obesity.10 For reasons that are still unclear, visceral obesity elicits greater SNS activation than does subcutaneous obesity. In most cases MSNA has been measured rather than RSNA, the primary pathway by which the SNS causes chronic obesity hypertension. Because there is heterogeneity of autonomic outflow to different organs, measurements of MSNA activity may not always reflect RSNA. Studies by Esler et al.61 indicate that obese hypertensive subjects generally have increased RSNA, as assessed by the norepinephrine spillover method, although studies comparing different ethnic groups are limited. Thus, additional studies are needed to assess factors that influence the relationships among visceral obesity, RSNA, and hypertension in different populations.

**Role of Efferent and Afferent Renal Nerves in Obesity Hypertension**

Considerable evidence suggests that the chronic BP effects of SNS activation in obesity are mediated mainly by renal nerves. Bilateral RDN greatly attenuated sodium retention and development of hypertension in obese dogs fed a high-fat diet.57 RDN also returned BP to nearly normal levels in established obesity hypertension in dogs61 (Figure 5). Even partial RDN (42% reduction in renal norepinephrine) using catheter-based radiofrequency ablation substantially reduced BP in obese dogs.69 Similar results have been found in obese humans with resistant hypertension, in which catheter-based radiofrequency RDN consistently lowered office BP by 25 to 30 mm Hg systolic BP and 10 to 12 mm Hg diastolic BP for ≤24 months.70,71 When 24-hour ambulatory BP was measured in a subgroup of patients, the reductions in BP after RDN averaged −11/−7 mm Hg systolic/diastolic BP.69 Although, a recent trial failed to find a major effect of RDN on BP, compared

![Figure 5. Mean arterial pressure and heart rate responses to bilateral renal denervation in dogs with established obesity hypertension.](https://example.com/figure5.png)

Obesity was induced by feeding a high-fat diet for 46 days before surgical denervation of both kidneys. Lean control values before beginning the high-fat diet are shown by the open bars. Role of Leptin in Obesity-Induced SNS Activation and Hypertension

Acute and Chronic Effects of Leptin on RSNA and BP

Shortly after leptin’s discovery in 1994, investigators found a positive association between plasma leptin concentration and MSNA activity and that acute leptin administration in rodents increased SNS activity in brown adipose tissue (BAT), the adrenal gland, and the kidneys. More recent studies indicate that acute hyperleptinemia increases MSNA in humans. Although these findings suggest a possible role for leptin in controlling renal function and BP, acute injections of leptin have little effect on BP, despite increasing SNS activity, perhaps due, in part, to counterbalancing vasodilator effects of nitric oxide (NO), which is also stimulated by leptin.

We demonstrated, however, that chronic increases in plasma leptin levels, comparable with those found in severe obesity, caused sustained increases in BP and HR in rodents. Aizawa-Abe et al subsequently reported increased BP in transgenic mice with ectopic leptin overexpression in the liver. Leptin-mediated increases in BP occur gradually during several days, consistent with modest increases in SNS activity that are not sufficient to directly cause vasoconstriction but sufficient to increase renal sodium reabsorption. The BP effects of leptin were completely abolished by combined α/β-adrenergic receptor blockade; in fact, after adrenergic blockade leptin infusion lowered BP and HR, perhaps because of weight loss or stimulation of NO.

The chronic hypertensive effect of leptin in lean rodents is modest and some investigators have reported no changes in BP during leptin infusions. However, chronic hyperleptinemia in lean animals also markedly reduces food intake and body weight, which would tend to lower SNS activity and BP. Moreover, leptin stimulates NO production, which opposes increases in BP. After blocking NO synthesis the chronic effects of leptin to cause hypertension and tachycardia were markedly amplified, despite reduced food intake and weight loss.

To the extent that obesity causes endothelial dysfunction and impaired NO release, as well as resistance to the anorexie and weight loss effects of leptin, one might predict enhanced BP effects of leptin in obese subjects, if the effects on SNS activity are maintained.

Most of the available data on BP effects of leptin are from rodents and leptin’s effects on SNA and BP in humans have not been extensively studied. In a randomized, double-blind, placebo-controlled study in overweight or obese humans, Zelissen et al reported that administration of recombinant leptin for 12 weeks did not raise BP, although they also observed no significant changes in body weight compared with control subjects. Brook et al observed that acute leptin administration in lean humans did not raise BP, a finding that is not surprising in view of previous studies showing that leptin’s effects on BP require several days to manifest.

A role for endogenous leptin in obesity hypertension is supported by the finding that administration of a leptin receptor (LepR) antagonist reduced BP and renal SNS activity in obese rabbits fed a high-fat diet. Similar studies have not, to our knowledge, been conducted in humans. However, the limited available information suggests that acute leptin administration...
stimulates SNS activity in humans,\textsuperscript{85} similar to findings in experimental animals.\textsuperscript{17} Overall, the current data suggest that leptin, at levels comparable with those found in obesity, raises BP and RSNA in experimental animals.\textsuperscript{93} However, if leptin is administered ICV, bypassing the blood brain barrier, food intake is substantially decreased in obese rodents fed a high-fat diet.\textsuperscript{101} This suggests that the attenuated response to leptin in obesity is partly due to defective transport, or saturation of transport, of leptin across the blood brain barrier.\textsuperscript{104} However, obese subjects have higher cerebrospinal fluid leptin levels compared with lean subjects\textsuperscript{102} suggesting that obesity also causes resistance to leptin signaling, likely related to a post-receptor defect.\textsuperscript{103}

To the extent that obesity induces global leptin resistance, one might expect attenuation of leptin’s effects on SNS activity and BP, as well as attenuation of its anorexigic effects. However, obesity has been suggested to induce selective leptin resistance, whereby leptin’s effects to increase RSNA are preserved while appetite suppression is attenuated.\textsuperscript{85} In obese mice, leptin’s anorexigic effects were blunted, whereas the acute effects to increase RSNA were preserved.\textsuperscript{104} Unfortunately, few studies have tested whether there is resistance to the chronic effects of hyperleptinemia on BP and SNS activity in obese compared with lean subjects. Also, the CNS pathways and cell signaling mechanisms that underlie selective leptin resistance in obesity are poorly understood and represent an important area for further investigation.

**Molecular Mechanisms for Leptin’s Differential Effects on BP and Metabolic Function**

The LepR is a cytokine receptor that activates Janus tyrosine kinase 2 (JAK2). After binding to its CNS receptors, leptin increases activity of Janus tyrosine kinase 2 leading to subsequent activation of 3 major intracellular pathways (Figure 6): (1) phosphorylation of tyrosine 1138 to recruit latent signal transducer and activator of transcription 3 (STAT3) to the LepR–Janus tyrosine kinase 2 complex, causing phosphorylation and nuclear translocation of STAT3 to regulate transcription, (2) insulin receptor substrate 2 phosphorylation activates phosphatidylinositol 3-kinase, which may elicit rapid nongenomic effects on neuronal activity and neuropeptide release, and (3) tyrosine 985 phosphorylation, which recruits the Src homology-2 tyrosine phosphatase to activate mitogen-activated protein kinase.

Deletion of each of these CNS signaling pathways causes increased adiposity, but only neuron-specific STAT3 deletion recapitulates the obese phenotype found in leptin-deficient mice.\textsuperscript{105} In addition to its importance in regulating body weight, STAT3 signaling also contributes to leptin’s chronic effects on BP. Deletion of STAT3 specifically in proopiomelanocortin neurons attenuated leptin’s effect to raise BP but had only minor effects on food intake and energy expenditure.\textsuperscript{106} These observations suggest that leptin-mediated activation of STAT3 in proopiomelanocortin neurons is important for BP regulation, whereas STAT3 activation in other neuronal types is more important in mediating leptin’s effects on appetite and energy expenditure.

The insulin receptor substrate 2–phosphatidylinositol 3-kinase pathway may also mediate leptin’s effect on SNS activity and BP. Pharmacological blockade of phosphatidylinositol 3-kinase abolished the acute effects of leptin on RSNA.\textsuperscript{107} CNS deletion of insulin receptor substrate 2 signifying also attenuated the chronic BP effects of leptin but caused only moderate obesity and did not alter the anorexic responses to leptin.\textsuperscript{108} These observations suggest that insulin receptor substrate 2–phosphatidylinositol 3-kinase signaling contributes modestly to body weight regulation but mediates at least part of leptin’s effects on SNS activity and BP.

Deletion of Src homology-2 tyrosine phosphatase in the entire CNS or specifically in the forebrain causes early onset obesity associated with hyperphagia and impaired glucose regulation.\textsuperscript{109} Also, the chronic BP effects of leptin were attenuated in mice...
are important sites for leptin’s effects on RSNA, BP, and glucose but mediate only a small fraction of leptin’s anorexic effects. Further studies are needed, however, to ascertain how these pathways are regulated in obesity and if their differential activation contributes to selective leptin resistance.

Role of Protein Tyrosine Phosphatase 1B and Suppressor of Cytokine Signaling 3 as Negative Regulators of Leptin’s Effects on SNS Activity and BP

As discussed previously, LepR activation causes phosphorylation of tyrosine residues on the LepR, including tyrosine 1138, which activates the STAT3 pathway and, like PTP1B, is a negative regulator of LepR signaling. One of the pathways that is regulated by the STAT3 pathway is protein tyrosine phosphatase 1B (PTP1B), which dephosphorylates Janus tyrosine kinase 2 (JAK2), tyrosine kinase, leading to the autophosphorylation of tyrosine residues on JAK2 and phosphorylation of Tyr985 and Tyr1138. Phosphorylation of Tyr985 activates Src homology-2 tyrosine phosphatase (SHP2) and mitogen-activated protein kinase (MAPK) and phosphorylation of Tyr1183 activates STAT3.

PTP1B deletion raised BP by SNS activation, even in the absence of high levels of leptin, suggesting that this pathway may also modulate SNA through other mechanisms besides leptin signaling.

Suppressor of cytokine signaling 3 (SOCS3) expression is regulated by the STAT3 pathway and, like PTP1B, is a negative regulator of LepR signaling that may contribute to leptin resistance in obesity (Figure 6). SOCS3 deficiency increases leptin sensitivity and attenuates obesity development in mice fed a high-fat diet. The importance of SOCS3 signaling in regulating SNS activity and BP, however, is unclear. Together, PTP1B and SOCS3 could play an important role in modulating the appetite, metabolic, and cardiovascular actions of leptin and contribute to the development of selective leptin resistance in obesity. However, additional studies are needed to determine how obesity alters PTP1B and SOCS3 expression and the role of these pathways in cardiovascular regulation.

Other factors associated with obesity, such as endothelial dysfunction and impaired NO release, also selectively amplify the leptin’s effects on SNS activity and BP. Thus, obesity induces complex pathophysiological events that not only modulate leptin signaling but also elicit changes in renal, vascular, and SNS function that contribute to unaltered, or even augmented, effects of leptin on SNS activity and BP (Figure 7), whereas leptin’s action on appetite, energy expenditure, and glucose homeostasis are attenuated.

Sympathetic Activity and BP Regulation in Obese, Leptin-Deficient Patients

Mice with leptin deficiency (ob/ob) mice have severe obesity, insulin resistance, hyperinsulinemia, and dyslipidemia but lower BP and reduced SNS activity compared with lean mice. Moreover, leptin infusion in ob/ob mice increased BP, despite reducing body weight.

Humans with leptin deficiency also exhibit early onset morbid obesity and many features of the metabolic syndrome. Although BP and SNS activity have been assessed in only a few
leptin-deficient humans, they generally are not hypertensive and do not have increased SNS activity. Of 4 individuals with leptin gene mutations who were studied by Ozata et al.,114 3 had normal BP despite severe obesity. One patient had elevated BP associated with high levels of adrenocorticotropic hormone that could have contributed to the hypertension. However, all these leptin-deficient individuals had sympathetic hypofunction as evidenced by postural hypotension, attenuated RAAS responses to upright posture, and reduced BP responses to cold pressor tests. We interpret these observations to be mainly consistent with observations in ob/ob mice, which have normal or reduced BP, despite severe obesity, insulin resistance, and dyslipidemia. Collectively, clinical and experimental observations support the concept that leptin, as a link between obesity, increased SNS activity, and elevated BP although data on leptin's chronic BP effects in humans are still limited.

Role of CNS Proopiomelanocortin Pathway in Obesity-Induced SNS Activation and Hypertension

The CNS proopiomelanocortin pathway is a major regulator of appetite, energy expenditure, and body weight. Proopiomelanocortin-expressing neurons are located in the ARC and send projections to neurons in the paraventricular nucleus and lateral hypothalamus where they release α-melanocyte-stimulating hormone, an agonist for melanocortin 3/4 receptors (MC3/4Rs)115 (Figure 6). The brain stem nucleus tractus solitarius also contains proopiomelanocortin neurons and MC3/4R that may be important in regulating energy balance.116

Increased food intake and weight gain stimulate proopiomelanocortin neurons and MC3/4R signaling, whereas negative energy balance reduces activity of this pathway. The importance of melanocortins in regulating energy balance is demonstrated by the finding that defects of proopiomelanocortin neuronal function or MC4R signaling cause severe obesity.117 Although MC3R regulates energy expenditure, MC4R is much more important in regulating appetite and body weight. MC4R deficiency, for example, causes severe obesity, whereas MC3R deficiency causes only mild increases in body weight.118 Mutations of MC4R cause 5% to 6% of early onset, morbid obesity in children, illustrating the powerful role of this pathway in body weight regulation.119

Activation of CNS Proopiomelanocortin-MC4R Pathway Increases SNS Activity and BP

In addition to regulating energy balance, the CNS proopiomelanocortin-MC4R system may contribute to obesity-induced SNS activation and hypertension. Chronic pharmacological activation of CNS MC4R in rats increases BP while reducing appetite and body weight.120 The rise in BP after chronic activation of MC4R is abolished after α/β-adrenergic blockade indicating that it is because of increased adrenergic activity.121 Conversely, blockade of CNS MC4R in rodents causes voracious feeding, rapid weight gain, and reduces rather than increases BP.122 MC4R-deficient mice are also hyperphagic, obese, and have many features of the metabolic syndrome but are not hypertensive on normal or high-salt diets.123

The BP-lowering effects of MC4R antagonism are especially pronounced in spontaneously hypertensive rats, a genetic model of hypertension characterized by increased SNS activity.122 CNS antagonism of MC4R for 12 days caused a much greater reduction in BP in spontaneously hypertensive rats than in normotensive Sprague-Dawley or Wistar-Kyoto rats, despite marked increases in food intake, weight gain, and insulin resistance; the fall in BP in spontaneously hypertensive rats after MC4R blockade was similar to that achieved with α/β-adrenergic blockade. These observations suggest that MC4R activation contributes to tonic SNS activation and may be necessary for rapid weight gain to increase BP.

Studies in humans also suggest that MC4R activation contributes to obesity-induced hypertension. Hypertension prevalence is lower in MC4R-deficient humans compared with control subjects, despite severe obesity and associated metabolic disorders.124,125 Even after exclusion of patients taking antihypertensive medications, BP, HR, and 24-hour norepinephrine excretion were significantly lower in MC4R-deficient subjects than in control subjects. Moreover, administration of a synthetic MC4R agonist increased BP, similar to the responses observed in rodents. Thus, in humans and rodents, chronic activation of MC4R raises BP and a functional proopiomelanocortin-MC4R system seems to be necessary for obesity to increase SNS activity and BP.

Proopiomelanocortin-MC4R Regulates BP in Nonobese Subjects, Independent of Leptin

The CNS proopiomelanocortin-MC4R pathway may increase SNS activity in response to additional stimuli besides leptin and obesity. MC4R blockade markedly reduced BP in spontaneously hypertensive rats, a nonobese model of hypertension associated with increased SNS activity.122 MC4R antagonism also reduced BP in obese Zucker rats with defective LepR signaling126 and attenuated BP effects of other peptides besides leptin, including nesfatin-1 and neuronostatin.127,128 Also, MC4R blockade attenuated hypertension associated with inhibition of NO synthesis but did not lower BP in Ang II hypertensive, which is associated with decreased RSNA.129 Studies in humans also show that increased MSNA during hypoxic stress is attenuated in MC4R-deficient subjects.130 These observations support the concept the proopiomelanocortin-MC4R
pathway may contribute to SNS activation during acute stress, as well as during chronic increases in SNS activity, and that this system plays a more fundamental role controlling SNS activity and BP than previously appreciated.

**CNS Centers for BP and SNS Regulation by Proopiomelanocortin-MC4R**

The CNS regions with the greatest abundance of MC4R are the paraventricular nucleus, lateral hypothalamus, the amygdala, the dorsal motor complex, which includes the nucleus tractus solitarius and the dorsal motor nucleus of the vagus, and preganglionic sympathetic neurons of the intermediolateral nucleus, which are all important sites for autonomic regulation (Figure 6). However, the specific brain regions where MC4R are most important in regulating SNS activity and BP are still unclear. Much of what is known comes from acute studies where MC4R agonists and antagonists have been injected into discrete CNS nuclei of anesthetized animals. Microinjection of an MC4R agonist into the paraventricular nucleus, for example, increased RSNA and BP, and the effect of hyperinsulinemia to acutely raise lumbar SNS activity was prevented by blockade of MC4R in the paraventricular nucleus.

The limited studies that have examined chronic cardiovascular actions of MC4R in specific neuronal populations suggest a role for MC4R on cholinergic preganglionic parasympathetic and sympathetic neurons in contributing to obesity hypertension. MC4R on proopiomelanocortin neurons may also play a role in modulating proopiomelanocortin activity and autonomic function. Rescue of MC4R function specifically in proopiomelanocortin neurons of mice with whole-body MC4R deficiency partially restored the BP response to acute stress, suggesting that MC4R may serve to autopotentiate proopiomelanocortin neuronal activity. However, the specific neurons that mediate the effects of MC4R on SNS activity and BP in obesity are still largely unknown.

**Signaling Pathways That Mediate Effects of MC4R Activation on BP and Metabolic Functions**

The MC4R is a G protein-coupled receptor that increases cAMP phosphorylation and activates protein kinase A; blockade of these intracellular pathways attenuates or abolishes MC4R actions. Although alternative cAMP-independent mediators of MC4R have been proposed, their physiological importance is unknown.

Previous studies of potential downstream mediators have generally been acute, lasting for only minutes to a few hours. Pharmacological activation of MC4R increased brain-derived neurotrophic factor protein in the dorsal motor nucleus of the vagus of rats, and the acute effect of an MC4R antagonist injected in the 4th ventricle to increase food intake was blocked by coadministration of brain-derived neurotrophic factor. Also, MC4R-mediated reductions in food intake and increases in BP were attenuated by previous CNS injection of an anti–brain-derived neurotrophic factor antibody. Other candidates, such as corticotrophin-releasing hormone, melanin-concentrating hormone (MCH), and oxytocin have also been suggested to contribute to MC4R’s actions on appetite. However, it is still unclear if they mediate the BP effects of MC4R activation.

Thus, the CNS proopiomelanocortin-MC4R pathway regulates appetite, energy expenditure, autonomic nervous system activity, and cardiovascular responses to stress, among many other important functions. However, the brain regions and downstream pathways that mediate MC4R actions are only beginning to be elucidated.

**CKD May Amplify the Effect of Obesity on Hypertension**

In addition to increasing BP by renal compression and activation of the RAAS and SNS, obesity may eventually cause CKD that amplifies the hypertension and makes it more difficult to control. The effect of obesity on CKD is obvious when one considers that type II diabetes mellitus and hypertension, both of which are closely associated with obesity, account for >70% of end-stage renal disease. Also, the rapid rise in CKD in the past 3 decades has paralleled increasing obesity and there is evidence that obesity may be an independent risk factor for CKD, beyond its effects to cause hypertension and diabetes mellitus.

In a study of ~6500 nondiabetic participants, increasing BMI and waist circumference were associated with reduced estimated glomerular filtration rate and CKD. Abdominal obesity was associated with higher risk of renal insufficiency even after adjustment for dyslipidemia, hyperglycemia, BP, and BMI in patients with essential hypertension. In a retrospective analysis of 320252 adults followed for 15 to 35 years, the rate of end-stage renal disease increased stepwise as BMI increased and this relationship remained after adjustment for BP, diabetes mellitus, smoking, age, and several other variables.

Early in development of obesity and even in obese children, there is often interstitial fibrosis, microalbuminuria or proteinuria, expansion of mesangial matrix, glomerulomegaly, focal segmental glomerular sclerosis, and podocyte disorder associated with glomerular hyperfiltration. As obesity and its associated hypertension and metabolic abnormalities are sustained, glomerular hyperfiltration subsides and may be replaced by declining glomerular filtration rate associated with nephron loss. With nephron loss, there is increasing salt-sensitivity of BP. Obesity also aggravates the deleterious effects of other primary kidney insults, including unilateral nephrectomy, kidney transplantation, unilateral renal agenesis, and immunoglobulin A nephropathy.

Although the mechanisms by which obesity causes renal injury, in addition to hypertension and diabetes mellitus, are still unclear and beyond the scope of this review, multiple factors have been proposed, including inflammation, mitochondrial dysfunction, oxidative stress, dyslipidemia and lipotoxicity caused by fat infiltration into and around the kidneys. Regardless of the precise causes of obesity-induced CKD, it is likely that the gradual decline in kidney function helps to explain why most patients with treatment-resistant hypertension are also overweight or obese. With declining renal function, adequate BP control becomes increasingly challenging.
Summary and Perspectives

There is overwhelming evidence that excess weight gain and visceral obesity are major causes of hypertension, perhaps accounting for as much as 65% to 75% of the risk for human essential hypertension. Although the mechanisms of obesity-induced hypertension are still being intensively studied, research in experimental animals and humans suggest important roles for impaired renal-pressure natriuresis because of physical compression of the kidneys and activation of the RAAS and SNS. As obesity and its metabolic and hemodynamic consequences are sustained during many years, renal injury gradually makes the hypertension more severe and more resistance to therapy.

Although weight loss is helpful in managing hypertension, many obese patients are unable to sustain adequate weight loss through lifestyle modifications and there are few available drugs that safely and effectively produce adequate long-term weight loss. Current therapeutic approaches are, therefore, aimed mainly at treating the hypertension and metabolic consequences of obesity, including diabetes mellitus, dyslipidemia, and inflammation. Specific guidelines for treating obesity-associated hypertension, in addition to the recommendation of reducing weight, are needed.

The most important therapeutic goal for obese hypertensive patients should be to treat their underlying causes of obesity. However, the physiological and behavioral factors that regulate energy balance are still not well understood, despite an explosion of obesity-related research in the past 2 decades and the discovery of many adipokines, gastrointestinal hormones, and CNS pathways that influence food intake and energy expenditure. Unfortunately, the most powerful known mechanisms that control energy balance and adiposity, such as leptin and the CNS melanocortin system, also tend to increase BP and HR. Although further research is needed to better understand the molecular pathways that link metabolic and cardiovascular regulation, the rapid advances that are occurring in this field provide reasons to be optimistic that more effective therapies for obesity will be developed in the near future.
