DPP4 in Cardiometabolic Disease
Recent Insights From the Laboratory and Clinical Trials of DPP4 Inhibition

Jixin Zhong, Andrei Maiseyeu, Stephen N. Davis, Sanjay Rajagopalan

Abstract: The discovery of incretin-based medications represents a major therapeutic advance in the pharmacological management of type 2 diabetes mellitus (T2DM), as these agents avoid hypoglycemia, weight gain, and simplify the management of T2DM. Dipeptidyl peptidase-4 (CD26, DPP4) inhibitors are the most widely used incretin-based therapy for the treatment of T2DM globally. DPP4 inhibitors are modestly effective in reducing HbA1c (glycated hemoglobin) (≈0.5%) and while these agents were synthesized with the understanding of the role that DPP4 plays in prolonging the half-life of incretins such as glucagon-like peptide-1 and gastric inhibitory peptide, it is now recognized that incretins are only one of many targets of DPP4. The widespread expression of DPP4 on blood vessels, myocardium, and myeloid cells and the nonenzymatic function of CD26 as a signaling and binding protein, across a wide range of species, suggest a teleological role in cardiovascular regulation and inflammation. Indeed, DPP4 is upregulated in proinflammatory states including obesity, T2DM, and atherosclerosis. Consistent with this maladaptive role, the effects of DPP4 inhibition seem to exert a protective role in cardiovascular disease at least in preclinical animal models. Although 2 large clinical trials suggest a neutral effect on cardiovascular end points, current limitations of performing trials in T2DM over a limited time horizon on top of maximal medical therapy must be acknowledged before rendering judgment on the cardiovascular efficacy of these agents. This review will critically review the science of DPP4 and the effects of DPP4 inhibitors on the cardiovascular system. (Circ Res. 2015;116:1491-1504. DOI: 10.1161/CIRCRESAHA.116.305665.)

Key Words: cardiovascular diseases ■ diabetes mellitus ■ DPP4 protein, mouse ■ glucagon-like peptide-1 ■ incretins

The growing burden of type 2 diabetes mellitus (T2DM) worldwide represents one of the most important challenges for global health. More than 50% of the risk of mortality from T2DM is attributable to cardiovascular causes, with T2DM contributing significantly to death and disability-adjusted life years. Although diet and lifestyle approaches are fundamental to the treatment of risk in T2DM, these treatments often fail in many patients necessitating pharmacological approaches. Dipeptidyl peptidase-4 (DPP4, also known as CD26) is a widely expressed glycoprotein that has gained attention owing to its role in the catalytic degradation of incretins such as glucagon-like peptide-1 (GLP-1) and as a receptor for the Middle Eastern respiratory syndrome (MERS) virus. The development of DPP4 inhibitors (DPP4i) as a class of antidiabetic medications was predicated on the simple notion that these drugs would raise GLP-1/gastric inhibitory peptide (GIP) levels resulting in enhancement of insulinotropic effects of glucose. This rather simple construct is now replaced with a much more nuanced understanding of this protein. In this review, we will summarize the structure and function of DPP4 and its known role in physiology. We will review its importance in the pathophysiology of cardiometabolic disorders and provide the evidence to date, on the effects of DPP4 inhibition, both from the context of experimental models, mechanistic human studies, and recent clinical trial evidence on cardiovascular outcomes.

Overview of DPP4 Biology and Regulation

Human DPP4 is a 766 amino acid single-pass type II integral transmembrane glycoprotein that belongs to S9b DPP family, which also include quiescent cell proline dipeptidase (also called DPP2), fibroblast activation protein, DPP8, and DPP9. Monomeric DPP4 has a short N-terminal cytoplasmic portion (6 residues, AA 1–6), a 22-residue transmembrane domain (AA7–29) and an extracellular domain, comprised an 8-blade β-propeller (Arg54–Asn497) and a large α/β-hydrolase domain (Gln508-Pro766) responsible for binding to adenosine deaminase (ADA) and matrix proteins such as fibronectin and collagen.2,3 Residues 630, 708, and 740 in the α/β-hydrolase domain are critical for catalytic function of DPP4. Although the C-terminal α/β-hydrolase domain is relatively conserved, the N-terminal 8-blade β-propeller domain demonstrates sequence...
variability. The catalytic pocket responsible for cleavage of several protein substrates is 8 Å and contained within a 15 Å wide opening at the interface between its hydrolase and propeller domains. Residue 294 and residues 340 to 343 within the cysteine-rich segment of DPP4 is essential for ADA binding. DPP4 exists as a monomer, homodimer, or homotrimer on the cell surface, with the homodimer representing the predominant catalytically active form. DPP4 is subject to post-translational modification via glycosylation and N-terminal sialytion, both of which have been suggested to regulate catalytic activity. DPP4 is cleaved from membrane-bound DPP4. Soluble DPP4 (sDPP4) lacks the cytoplasmic and transmembrane domains. Residue 294 and residues 340 to 343 within the cysteine-rich segment of DPP4 is essential for ADA binding. The best known noncatalytic function of DPP4 is to provide costimulation for T cells by interacting with ADA. Activation of DPP4 induced tyrosine phosphorylation of molecules downstream of T cell receptor (TCR)/CD3, such as p56

Physiological Role of Catalytic Function of DPP4

DPP4 exerts its peptidase function by removing N-terminal dipeptides displaying proline, alanine, or serine as the penultimate (P1) amino acid residue. Inactivation of GIP and GLP-1 suppress glucagon release, decrease gastric emptying, promote β-cell proliferation, and suppress β-cell death. Pharmacological inhibition of DPP4 enzymatic activity improves glucose tolerance in wild-type, but not in Dpp4-/- mice. Interestingly, DPP4 inhibition improves glucose tolerance in Glp1r-/- mice, indicating that DPP4 contributes to blood glucose regulation by additional substrates such as GIP or through GLP-1R-independent mechanisms. In addition to gut-derived peptides GLP-1 and GIP, the other substrates include a variety of neuropeptides and chemokines. A recent study suggests in addition to chemokines other cytokines such as GM-CSF, G-CSF, IL-3, and erythropoietin could also be cleaved by DPP4. The catalytic activity of DPP4 and its substrates (Figure 1) have been extensively reviewed elsewhere and we will not go into detail here.

Physiology of Noncatalytic Function of DPP4

In addition to its well-known peptidase activity, DPP4 also possesses noncatalytic functions through its interaction with a ligands including ADA, caveolin-1, fibronectin, and CXCR4 (CXC chemokine receptor 4).

Interaction With ADA and Mediation of T-Cell Costimulation

The best known noncatalytic function of DPP4 is to provide costimulation for T cells by interacting with ADA. Activation of DPP4 induced tyrosine phosphorylation of molecules downstream of T cell receptor (TCR)/CD3, such as p56

Figure 1. Dipeptidyl peptidase-4 (DPP4) functions and structure. DPP4 consists of a 6-amino-acid (AA) cytoplasmic tail, a 22-AA transmembrane domain and a large extracellular domain. The extracellular domain is responsible for the dipeptidase activity and binding to its ligands such as adenosine deaminase (ADA) and fibronectin. BNP indicates brain natriuretic peptide; G-CSF, granulocyte colony-stimulating factor; GIP, gastric inhibitory peptide; GLP, glucagon-like peptide-1; GM-CSF, granulocyte-macrophage colony-stimulating factor; GRP, gastrin-releasing peptide; IP-10, interferon gamma-induced protein 10; MDC, macrophage derived chemokine; MIG, monokine induced by IFN-γ; NPY, neuropeptide Y; PYY, peptide YY; RANTES, regulated on activation, normal T-cell expressed and secreted; and SDF-1, stromal-cell-derived factor-1.
Interestingly, murine and rat DPP4 do not bind ADA. Using site-directed mutagenesis, Leu-294 and Val-341 were identified as 2 ADA-binding sites in human DPP4. Leu-294 and Val-341 are positioned at the outer strand of the tetramerization blade IV and blade V, respectively. Therefore, ADA binding has been thought to interfere with tetramerization. Similarly, the glycosylation of Asn281 is likely to influence ADA binding. Thus, tetramerization and glycosylation may serve as control mechanisms for ADA binding and may explain why murine DPP4 lacks glycosylation sites and may not bind ADA.

**Novel Roles for DPP4**

In 2013, DPP4 was identified as a functional receptor for the spike protein of a novel betacoronavirus species, the Middle Eastern Respiratory Syndrome (MERS) coronavirus in human and bat cells. The engagement of the MERS coronavirus spike protein S with CD26 mediates viral attachment to host cells initiating infection. The viral receptor-binding domain recognizes blades IV and V of the DPP4 β-propeller. The residues identified in the virus–DPP4 interface are also involved in ADA binding. As the ADA–DPP4 interaction has been shown to induce costimulatory signals in T cells, this may indicate a possible manipulation of the host immune system by MERS coronavirus through competition for the ADA-recognition site. DPP4 receptor binding domain may thus represent a potential treatment strategy for MERS coronavirus infection.

DPP4 on T cells may also interact with caveolin-1 on APCs (antigen-presenting cells), resulting in its phosphorylation and leads to activation of downstream NF-$\kappa$B. Activated NF-$\kappa$B in turn upregulates CD86. This process has been suggested to be involved in the pathogenesis of inflammatory disorders. DPP4 has been reported to bind multiple components of extracellular matrix such as collagen, fibronectin, and the HIV-1 Tat protein. Interactions with matrix components may play a role in sequestration of DPP4 and allow additional functions such as matrix remodeling, metastasis, and chemotaxis.

**DPP4 in Diabetes Mellitus**

**DPP4 Expression and Diabetes Mellitus**

DPP4 is an important regulator of postprandial glucose via degradation of GLP-1 and GIP. DPP4 rapidly inactivated by DPP4, resulting in a short half-life (<2 minutes for GLP-1 and <2 minutes in rodents or 7 minutes in human for GIP). In contrast to early reports suggesting that GLP-1 levels are decreased in T2DM, recent studies suggest that, in general, patients with T2DM do not exhibit reduced GLP-1 secretion in response to an oral glucose tolerance test or meal test. However, deteriorating glycemic control may be associated with reduced GLP-1 secretion. DPP4 enzymatic activity correlates with the degree of glucose homeostasis in T2DM. DPP4 expression in both visceral and subcutaneous adipose tissue positively correlates with body mass index, with visceral adipose tissue consistently displaying higher expression. DPP4 expression positively correlates with the amount of visceral adipose tissue, adipocyte size, inflammation, and HbA1c (glycated hemoglobin) and negatively correlates with glucose infusional rates during euglycemic–hyperinsulinemic clamp. Within adipose, adipocytes seem to secrete abundant DPP4 with levels exceeding that from macrophages. Ex vivo release of DPP4 from adipose tissue explants were higher in visceral adipose tissue than in subcutaneous adipose tissue with obese patients displaying higher DPP4 release than lean controls. Secreted DPP4 may in turn exert paracrine effects on insulin signaling in adipocytes and skeletal muscle cells. Among inflammatory cells, T-cell expression exceeds that of macrophages and dendritic cells (DCs). Expression of DPP4 increases in peripheral T cells and in the liver of patients with nonalcoholic fatty liver disease with levels correlating with insulin resistance. Interestingly, several widely used glucose-lowering medications such as metformin and thiazolidinedione have been reported to reduce circulating DPP4 and DPP4 on T cells. DPP4i also seem to exert effects on brown adipose tissue metabolism by increasing UCP-1 (uncoupling protein 1) and PGC-1a (peroxisome proliferator-activated receptor gamma coactivator 1-alpha) levels, through increase in GLP-1.

**Catalytic Inhibition of DPP4 Function in Diabetes Mellitus**

There are currently 4 DPP4i approved by the Food and Drug Administration (FDA) and 1 DPP4i approved by the European Medicines Agency: sitagliptin (FDA approved in 2006), saxagliptin (FDA approved in 2009), linagliptin (FDA approved in 2011), alogliptin (FDA approved in 2013), and vildagliptin (European Medicines Agency approved in 2007). They can be broadly divided into 2 classes based on structure: DPP4 dipeptidyl peptide structure mimetics and nonpeptidomimetics. The first class includes sitagliptin (7-amino acid based), vildagliptin, and saxagliptin (nitrile containing), whereas the nonpeptidomimetics include alogliptin (modified pyrimidinedione) and linagliptin (xanthine-based). There are several others in advanced clinical trials including dutogliptin and gemigliptin and at least 2 once weekly DPP4i are in advanced clinical trials. DPP4i demonstrate 0.4% to 0.8% lowering of HbA1c, with the degree of lowering depending on the baseline HbA1c, concomitant therapy, and patient population. In general, the glycemia lowering efficacy with DPP4i is lower than that with sulfonylureas, insulin, and thiazolidinediones, but they are significantly better tolerated and devoid of weight gain. The most frequently reported side effects of DPP4i include nasopharyngitis, upper respiratory tract infection, urinary tract infection, and headache. In contrast to other members of the class, linagliptin has a primarily nonrenal route of excretion and does not need dose adjustment in renal impairment. Several studies corroborate improvement in β-cell function indices including homeostasis model assessment β-cell function index, fasting proinsulin:insulin ratio, and insulin secretion rates in response to mixed meal challenge.

**Noncatalytic Interactions of DPP4 and Inflammation**

The mechanism by which DPP4 may potentiate inflammation in T2DM likely involves both its catalytic and noncatalytic function. There is good evidence suggesting a role for DPP4 noncatalytic function in the regulation of T-cell activation. DPP4 expression increases with functional maturation of DCs and macrophages from monocytes with a role for upregulation of CD86 expression and activation of the NF-$\kappa$B.
pathway. The interaction between DPP4 and ADA may also facilitate T-cell activation through regulation of pericellular adenosine levels. Jurkat cell (a T-cell line) with a DPP4 mutant devoid of ADA binding activity is sensitive to adenosine-mediated inhibition of T-cell proliferation, indicating that DPP4 on immune cells facilitates adenosine clearance by binding to ADA (Figure 2). In assays using T-cell/DC cocultures, adenosine dose-dependently suppresses T-cell proliferation, whereas preincubation of DCs with ADA relieved the inhibitory effect of adenosine in a dose-dependent manner. Small interfering RNA knockdown of DPP4 on DC suppresses proliferation of both CD4+ and CD8+ T cells while sitagliptin did not. Both T-cell receptor signaling and Signal transducer and activator of transcription 3 (STAT3), an important signaling molecule that regulates T-cell proliferation and activation, are regulated by DPP4-expressing DCs. STAT3 phosphorylation increases on T-cell activation, an effect suppressed by adenosine. Lymphocyte-specific protein tyrosine kinase (Lck), a Src family tyrosine kinase that is activated with TCR activation and allows binding and phosphorylation of ZAP-70 to mediate downstream signaling events, is prevented from being activated in T cells cocultured with DPP4 small interfering RNA-transfected DC (as suggested by an increase in phospho-Lck [Tyr505], the inactive form of Lck). These results suggest that DPP4 on antigen presenting and T cells may promote adipose inflammation and insulin resistance through its noncatalytic function. However, the precise extent to which noncatalytic function regulates inflammation independent of the catalytic function in T2DM will require experiments in animals expressing human DPP4 that additionally have mutations in enzymatic function as murine DPP4 lacks the ADA binding site.

**Figure 2.** Mechanisms by which dipeptidyl peptidase-4 (DPP4) modulates immune response of relevance to cardiovascular disease. DPP4 regulates immune response via multiple mechanisms that involve both adaptive and innate immune function. These include (1) control of pericellular adenosine levels: ATP or ADP is converted into AMP by membrane-bound CD39. AMP is further catalyzed by CD73 and produce adenosine. Adenosine is degraded by adenosine deaminase (ADA) bound to membrane-anchored DPP4. Accumulation of adenosine suppresses T-cell activation and proliferation; (2) ADA–DPP4 interaction provides costimulatory signaling for T-cell activation. By signaling through CD45, DPP4 enhances T-cell receptor signals to promote T-cell activation; (3) inactivation of glucagon-like peptide-1 (GLP-1), GLP-1 binds to GLP-1R and increases CAMP resulting in protein kinase A (PKA)–mediated suppression of ERK, JNK, and nuclear factor (NF)-κB; (4) activation of APCs by interaction with cavelin-1. DPP4 binds to cavelin-1 and activates IRAK and NF-κB, leading to the activation of APCs. APC indicates antigen-presenting cell; ERK extracellular signal-regulated kinase; IRAK IL-1 receptor-associated kinase; and JNK, c-Jun N-terminal kinase.

### Effects of DPP4 Inhibition on Cardiovascular System

**Effects of DPP4i on Endothelial Cells, NO, and Blood Pressure**

DPP4 is expressed on endothelial cells and seems to play a physiological role in the regulation of vascular tone and angiogenesis. Studies have suggested that DPP4/insulin axis has substantial implication in cardiovascular system (Figure 3). Incubation of human umbilical vein endothelial cells with DPP4i such as alogliptin and vildagliptin has been shown to result in endothelial nitric oxide synthase (eNOS) and Akt phosphorylation paralleled by a rapid increase in NO. DPP4 inhibition relaxes preconstricted aortic segments in a dose-dependent manner, responses unaffected by the GLP-1R antagonist, exendin 9–39. In 1 study, vascular relaxation was reduced by endothelial denudation, L-NG-nomethyl-arginine citrate, and by the soluble guanylate cyclase inhibitor ODQ, whereas a combination of L-NG-nomethyl-arginine citrate and blockers of calcium activated potassium channels completely obviated relaxation in response to DPP4 inhibition, suggesting that both eNOS and potassium channels mediated effects on vascular function. Inhibition of Src kinase decreased eNOS and Akt phosphorylation in response to DPP4 inhibition NO. DPP4 inhibition–mediated GLP-1R activation may also represent a mechanism for the blood pressure–lowering effect of DPP4i. However, the locus of GLP-1R activation is controversial. Although endothelial cells have been shown to express GLP-1R at least in some studies, at least in 1 study the antihypertensive effects of GLP-1R activation by liraglutide did not directly relax preconstricted aortic rings or increase cGMP. However, conditioned medium from liraglutide-treated hearts relaxed aortic rings in an endothelium-independent, GLP-1R–dependent manner. The decrease in BP involved an indirect natriuretic effect dependent on ANP release from the atria in a GLP-1R–dependent manner. Several other studies in animal models support a favorable effect of DPP4 inhibition in improving endothelial function and blood pressure. In contrast to the positive effects in animals, the effects of DPP4i on endothelial function in humans have been inconsistent. Although some of the inconsistency may relate to differences in improving endothelial function and blood pressure.
in end points, methodology, and patient characteristics, it is possible that these conflicting results may reflect differential alteration in the levels of substrates and their metabolites by DPP4i, which may vary depending on the study participants. In a double-blind study in T2DM, treatment with vildagliptin for 4 weeks improved forearm blood flow in response to intra-arterially delivered acetylcholine. In contrast, 2 studies using flow-mediated dilation of the brachial artery have shown opposite results with 1 study showing that both sitagliptin and alogliptin worsen flow-mediated dilation, whereas in another study sitagliptin improved flow-mediated dilation in association with an increase in CD34+ cells in another study.

Although earlier studies in small cohorts seem to suggest a favorable effect of DPP4i in reducing BP, these effects have not been consistently observed. An obvious explanation is that the magnitude of effect which is typically small (1–3 mm Hg) may not be easily observed in studies using clinic systolic blood pressure, particularly as a secondary end point. Indeed a large meta-analysis of published data on DPP4i using clinic BP does not support an effect on blood pressure. An alternate hypothesis that has been proffered relates to differential alteration of substrates of DPP4 such as NPY, which shifts the receptor affinity from Y1 to non-Y1 receptors. DPP4 inhibition has been demonstrated to enhance sodium excretion through interaction with the renal sodium hydrogen exchanger type 3 exchange protein and does so in both wild-type and Glp1r−/− mice. The mechanisms may relate to the physical association of the sodium hydrogen exchanger type 3 with DPP4 with inhibition of DPP4 catalytic activity, suppressing sodium hydrogen exchanger type 3-mediated NaHCO3 reabsorption in rat renal proximal tubule, resulting in increased Na+ excretion. Further the redistribution of the complex of DPP4–sodium hydrogen exchanger type 3 is thought to represent an adaptive mechanism in chronic hypertension. It has also been suggested that catalytic inactivation of natriuretic peptides such as brain natriuretic peptide by DPP4 may regulate blood pressure through natriuretic and vasodilatory effects. DPP4 converts brain natriuretic peptide (BNP) to produce BNP(3–32), which has reduced vasodilation and natriuretic effects. In humans, however, inhibition of DPP4 with sitagliptin acutely, does not potentiate BNP levels or its effects on forearm blood flow. In a post hoc analysis of SAVOR-TIMI, NT-proBNP level was not increased with Saxagliptin treatment and was lower when compared with placebo.

**DPP4 Inhibition in Angiogenesis and Stem Cell Homing**

Expression of DPP4 on Sca-1+lin− donor hematopoietic cells negatively regulates homing and engraftment vasculogenesis. By inhibiting DPP4 catalytic function or deleting DPP4, the transplantation and engraftment efficacy of hematopoietic stem cells was greatly enhanced. Stromal-cell–derived factor-1 (SDF-1) is a substrate for DPP4 and has been implicated in the mobilization and homing of hematopoietic cells in response to G-CSF treatment in experimental ischemia/infarction. DPP4-truncated SDF-1 not only loses its chemotactic activity but also blocks chemotactic effects of full-length SDF-1. Sitagliptin treatment in patients with T2DM results in a 2-fold increase of circulating EPC (endothelial progenitor cell) with concomitant increase in plasma SDF-1. Short-term treatment with DPP4i has also been demonstrated to increase SDF-1 levels and CD34+ cells. The increase in CD34+ cells corresponded to increased homing and deposition to an ischemic hindlimb preparation and infarcted myocardium. DPP4 may also regulate HSCs (hematopoietic stem cells) and HPCs (hematopoietic progenitor cells) by truncating multiple CSFs (other than SDF-1) with consequent loss of their activity. DPP4 knockout or pretreatment of HPCs from human cord blood or mouse bone marrow with DPP4i enhances the proliferative action of GM-CSF, G-CSF, IL-3, and erythropoietin. DPP4 deficiency or catalytic inhibition promotes hematopoiesis and bone marrow engraftment in mice after radiation or chemotherapy. Interestingly, DPP4-truncated CSFs blunt the activity...
of their respective full-length CSF, both in vitro and in vivo with the truncated GM-CSF, demonstrating a higher affinity to GM-CSF receptor. However, there were also studies showing that DPP4 inhibition reduces angiogenesis through inactivation of NPY(1–36). Truncation of NPY by DPP4 leads to a shift of receptor subtype specificity with cleaved NPY(3–36) binding to non-Y1 (Y2, Y3, and Y5) receptors. Production of NPY(3–36) is required for angiogenic activity as DPP4 inhibition by neutralizing antibody suppresses NPY-mediated endothelial cell migration in an endothelial wound assay.

Pharmacological inhibition of DPP4 catalytic function stimulates angiogenesis, enhances endothelial cell migration, aortic sprouting, and angiogenesis in in vivo assays. Src kinase–mediated eNOS-Akt activation in response to DPP4 inhibition seems to play an important role in the angiogenic response to DPP4 inhibition. The effects of DPP4 inhibition in enhancing angiogenesis in vitro are paralleled by an improvement in hindlimb blood flow in a hindlimb ischemia model. DPP4 inhibition has also been shown to improve healing of chronic foot ulcer in patients with T2DM, in parallel with increased HIF-1α (hypoxia-inducible factor) and VEGF (vascular endothelial growth factor) in the periphery of the ulcer and ulcer capillary density. Similarly, the angiogenic capacity of circulating progenangiogenic cells in patients with T2DM has been shown to be increased in vivo in response to DPP4 inhibitors.

Effects on Lipid Metabolism
Administration of DPP4i to hyperlipidemic mice reduces postprandial lipoprotein levels. The effects of DPP4i on lipoprotein metabolism have been reviewed extensively. A single dose of sitagliptin after a high-fat liquid formula administered under pancreatic clamp conditions decreased triglyceride-rich lipoproteins apoB48 concentration by reducing production rates in healthy subjects. The magnitude of lipid lowering seen with different DPP4i seems to be comparable and of a similar magnitude with that seen with the GLP-1 agonist exenatide.

In a 4-week single center, randomized double-blind study in T2DM, vildagliptin (n=31; 50 mg bid) reduced postprandial plasma triglyceride, chylomicron apoB48 after mixed meal challenge, without changes in apoB100. Vildagliptin also increased intact GLP-1, suppressed inappropriate glucagon secretion.

In a randomized cross-over study, alogliptin (25 mg/d, for 7 days) suppressed postprandial elevation of triglyceride, apoB48, and remnant lipoproteins.

In a double-blind crossover study, sitagliptin >6 weeks (100 mg/d) significantly decreased postprandial area plasma apoB48 triglyceride, and very-low-density lipoprotein-cholesterol.

In a randomized cross-over study >7 days of vildagliptin versus placebo, with microdialysis catheter-based analysis of metabolites, vildagliptin treatment was associated with a reduction in postprandial lactate and pyruvate production in the skeletal muscle with evidence of enhanced lipolysis. These effects may reflect improvement in hepatic glucose production by the liver because of obviation of insulin resistance by DPP4i and was supported by calorimetry suggesting increased energy expenditure and lipid oxidation rates.

Effects on Atherosclerosis
Several DPP4i have been shown to reduce atherosclerosis in experimental models (Online Table 1). These studies have all consistently noted a reduction in foam cell formation and inflammatory content. In at least 2 of these studies a reduction in migratory capacity of monocytes has been implicated. Pretreatment with DPP4i for 2 weeks in ApoE−/− mice markedly reduced the migration of labeled bone marrow–derived monocytes to atherosclerotic plaque in response to exogenous–administered TNFα and sDPP4. In vitro Boyden chamber assays using alogliptin and sitagliptin performed in the presence of nanomolar concentration of TNFα confirmed reduced monocyte migration in response to a CC chemokine ligand (CCL)-2 gradient, which was not inhibited by GLP-1 9–39. The effects of DPP4i include reduction in inflammatory gene expression and a reduction in monocytes and T cells. Given the effects of DPP4 in costimulation and regulation of adenosine, it may suggest a role for DPP4, independent of its effects on substrates such as GLP-1. GLP-1 has been shown to decrease monocyte migration in response to CCL-2 and regulated on activation, normal T-cell expressed and secreted in a concentration-dependent manner. GLP-1 may also exert anti-inflammatory effects via cAMP-dependent mechanisms, which may reduce NF-κB and Erk activation.

Infusion of exendin-4 for 4 weeks reduces neointimal formation, foam cells, and atherosclerotic lesion size. In support of a role for GLP-1 in DPP4-mediated effects, administration of antagonists to GLP-1 and GIP (exendin(9–39) and Pro(3) GIP) attenuated antiatherosclerotic effects of vildagliptin on atherosclerosis (Online Table I). In humans, 1 study noted a reduction in carotid intima media thickness progression with sitagliptin compared with placebo >12 months in newly diagnosed patients with T2DM with coronary artery disease.

Effect on Myocardial Function and Ischemia–Reperfusion
Genetic disruption of the Dpp4 gene in mice is not associated with baseline abnormalities in cardiac structure or function. Table 1 reviews the effects of DPP4i on models of ischemia reperfusion. In response to experimental infarction, Dpp4−/− mice exhibit improved survival with a trend toward reduction in infarct size. Hearts from Dpp4−/− mice contained higher levels of phosphorylated AKT, pGSK3, and ANP, well-known prosurvival pathways. In a postinfarction model, sitagliptin treatment led to an improvement in passive left ventricular compliance, increased endothelial cell density, reduced myocyte hypertrophy, and reduced collagen 1. Treatment with sitagliptin resulted in improved postinfarction survival without change in infarct size, an effect associated with upregulation of prosurvival pathways HO-1 and Akt, pathways activated by GLP-1. Whether the results in response to DPP4 inhibition are because of an increase of DPP4 target proteins such as GLP-1 cannot be definitively inferred from studies to date. Recent studies seem to contest the role of direct effects of GLP-1 on myocardial cells and invoke a role for GLP-1–dependent atrial natriuretic peptide synthesis from atrial cells, because myocytes do not seem to express GLP-1 receptors.

Composite indicates a composite defined as CV-related death, nonfatal MI, nonfatal stroke, or unstable angina requiring hospitalization. ACS indicates acute coronary syndrome; CARMELINA, Cardiovascular and Renal Microvascular Outcome Study With Linagliptin in Patients With Type 2 Diabetes Mellitus; CAROLINA, Cardiovascular Outcome Study of Linagliptin Versus Glimepiride in Patients With Type 2 Diabetes; CRF, cardiovascular risk factor; CV, cardiovascular; CVD, cardiovascular disease; EXAMINE, Cardiovascular Outcomes Study of Alogliptin in Patients With Type 2 Diabetes and Acute Coronary Syndrome; MACE, major adverse cardiac events (defined as a composite of CV death, nonfatal MI, and nonfatal stroke; these events were adjudicated by an independent cardiovascular end points committee); MI, myocardial infarction; SAVOR-TIMI 53, Does Saxagliptin Reduce the Risk of Cardiovascular Events When Used Alone or Added to Other Diabetes Medications; T2DM, type 2 diabetes mellitus; and TECOS, A Randomized, Placebo Controlled Clinical Trial to Evaluate Cardiovascular Outcomes After Treatment With Sitagliptin in Patients With Type 2 Diabetes Mellitus and Inadequate Glycemic Control.

heart failure. Pharmacological DPP4 inhibition in models of diabetic cardiomyopathy, pressure overload model of heart failure has been consistently shown to improve ventricular remodeling and survival as well as ameliorating severity of heart failure. Similarly, both pharmacological and genetic DPP4 inhibition reversed diabetic diastolic left ventricular dysfunction and pressure-overload–induced left ventricular dysfunction. Diabetes mellitus is well known to impair angiogenic ability through SDF-1α–dependent pathways in cardiac tissue. DPP4 inhibition (both pharmacological and genetic) reversed SDF-1α–dependent microvasculopathy and diabetes mellitus–associated diastolic left ventricular dysfunction. Improved left ventricular function assessed by ejection fraction, mitral annular systolic velocity, and peak systolic velocity has also been observed in humans with DPP4 inhibition (Sitagliptin, single dose or 4 weeks of treatment). Although the effects of DPP4 inhibition on heart failure have been directly attributed to increase in GLP-1, the extent to which these effects are driven by GLP-1 is unclear. This is especially true given recent evidence contesting the presence of GLP-1 receptors in the myocytes and dependence of atrial synthesis of ANP for GLP-1 effects. Moreover, the effects of GLP-1 itself are controversial. GLP-1 agonism has also been shown to increase left ventricular ejection fraction (all in short-term); however, reports on long-term cardiovascular effect of DPP4i and GLP-1 analogs are limited.

Effects on Renal Injury and CKD Progression

DPP4 inhibition has been shown to exert renoprotective effects characterized by reduction in oxidative stress, podocyte injury, mesenchymal expansion, fibrosis, and proteinuria in experimental models (Table 1). These effects seem to occur without changes in blood pressure or insulin sensitivity. Treatment with sitagliptin and linagliptin has also been shown to reduce proteinuria. In a 6-month open label trial in 35 patients, albumin:creatinine ratio was reduced by at least 2-fold in patients with a range of albumin excretion from normalalbuminuria to macroalbuminuria (urinary albumin:creatinine ratio >300). A pooled analysis of 4 completed studies (n=217) of subjects with T2DM and prevalent albuminuria (defined as a albumin:creatinine ratio of 30–3000 mg/g creatinine) receiving linagliptin on top of stable doses of RAAS (renin–angiotensin–aldosterone system) inhibitors demonstrated a modest 28% placebo-adjusted reduction in albumin:creatinine ratio at 6 months independent of blood pressure.

Sitagliptin protects renal function in patients with T2DM as evidenced by reduced urinary albumin-to-creatinine ratio. Renovascular response to angiotensin II may also be enhanced by DPP4 inhibition. Sitagliptin (1 μmol/L) significantly enhanced angiotensin II–induced increase of perfusion pressure in isolated kidneys from both lean (18.2±5.9 versus 3.4±1.3 mmHg) and obese (17.8±8.2 versus 5.5±1.3 mmHg) ZSF1 rats. Improvement in filtration barrier remodeling and suppression of fibrosis may also serve as alternative mechanisms of DPP4i in protecting renal function in chronic kidney disease.

Cardiovascular Clinical Trials With DPP4i

Online Table II lists completed and ongoing randomized controlled clinical trials with DPP4i. SAVOR-TIMI53 was designed as a superiority trial and failed to meet the prespecified superiority outcome of saxagliptin versus placebo in a high-risk patient population with established vascular disease and risk factors. In the EXAMINE (Cardiovascular Outcomes Study of Alogliptin in Patients With Type 2 Diabetes and Acute Coronary Syndrome) trial, designed as a safety trial in a high-risk postacute coronary syndrome population, the prespecified end point of noninferiority was met and alogliptin was noninferior to placebo with regards to cardiovascular outcomes. In both EXAMINE and SAVOR-TIMI53 trials, the primary outcome composed of cardiovascular death, myocardial infarction, and ischemic stroke was noninferior in DPP4i group when compared with placebo group. In both trials the median duration of follow-up was <4 years, the majority of whom were on evidence-based therapies. These factors are widely felt to have been responsible for lack of benefit with these
agents. In SAVOR-TIMI 53, baseline NT-proBNP was measured in 12,301 patients. More patients treated with saxagliptin were hospitalized for heart failure when compared with placebo (hazard ratio, 1.27; 95% confidence interval, 1.07–1.51; P=0.007). Differences in heart failure were seen in <6 months with rates at 12 months of 1.9% versus 1.3% (hazard ratio, 1.46, 95% confidence interval, 1.15–1.88; P=0.002, with no difference thereafter). Subjects at greatest risk for heart failure had prior heart failure, eGFR (estimated glomerular filtration rate) ≤60 mL/min, and elevated baseline levels of NT-proBNP (risk in highest NT-proBNP quartile of 2.1%). Whether the association with heart failure applies to other DPP4i will need to be addressed in ongoing cardiovascular outcome trials of DPP4i.139

Inconsistency with this finding, a slight increase of heart failure hospitalization was observed in patients with alogliptin compared with those with placebo (3.9% versus 3.3%; hazard ratio, 1.19; 95% confidence interval, 0.90–1.58) in EXAMINE trial, although no statistical significance was observed.140,141

The other authors report no conflicts.

Conclusions
The development of DPP4i has evolved from the understanding of its role in regulation of incretin hormones. However, the widespread expression of this molecule in a variety of cell types clearly underscores a previously unrecognized role for this molecule in physiological processes. Despite the plethora of enzymatic substrates that serve as targets, the inhibition of enzymatic function in animals and humans seems to be well tolerated and safe with modest reduction in HbA1c. The preponderance of evidence from inhibiting DPP4 enzymatic function in animal models of disease seems to suggest that salutary effects including in heart failure and in totality seem to suggest the possibility of beneficial cardiovascular effects in humans. At least 2 large randomized clinical trials focused on cardiovascular outcomes in high-risk patients with T2DM on best medical therapy seem to show no differences compared with placebo with regards to the composite end point of cardiovascular death, myocardial infarction, and stroke during a duration of <4 years of drug treatment. The noncatalytic function of DPP4, including its role as a costimulatory molecule and binding to several matrix proteins including ADA in humans, points to larger role for DPP4 outside of its catalytic function. Future mechanistic studies will need to focus on the relative contribution of the catalytic versus noncatalytic function in cardiometabolic disease, whereas clinical trials will need to address the heart failure safety signals and demonstrate a beneficial effect of this class in cardiovascular complications associated with T2DM.
