Effects of Low Oxygen and of Carbon Monoxide on the Renal Circulation in Unanesthetized Rabbits

By Paul I. Korner, M.D.

With the technical assistance of Yvonne Paseoe

The circulatory response of the normal unanesthetized rabbit to acute hypoxia differs from that of man or the dog.1-3 For the first few minutes after breathing low O2 mixtures, bradycardia and a small rise in blood pressure were observed.1 The steady state response following more prolonged exposure was variable with an increase in cardiac output and heart rate in some animals and persistent bradycardia and a reduction in cardiac output in others.2 In contrast to this variable response, man and the dog usually develop an increase in cardiac output and heart rate when breathing low O2 mixtures. The experiments of Bernthal et al.,4 Daly and Scott,5-7 and Downing et al.5 suggest that in the dog this response is not primarily the result of stimulation of the arterial chemoreceptors. When the carotid chemoreceptors were perfused with hypoxic blood in dogs with controlled ventilation, bradycardia, reduction in cardiac output and systemic vasoconstriction were observed.4-6 When chemoreceptor perfusion was carried out in the same animals during spontaneous respiration a variable response not unlike the picture in the conscious rabbit during the steady state was obtained; for example, under these conditions the heart rate remained unchanged, or increased or decreased.5-7 These results suggest that the circulatory effects of chemoreceptor stimulation in the dog may be modified in the spontaneously breathing animal.

In contrast to the variable effects of low O2 mixtures in the rabbit, breathing small concentrations of carbon monoxide in air resulted in a uniform increase in cardiac output, tachycardia and relatively little increase in respiratory minute volume.2 Breathing CO reduces the O2-carrying capacity of the blood and produces an "anemic" type of hypoxia at the tissue level. The results with CO in the rabbit were similar to the effects observed in man by Asmussen and Chiodi9 and in the dog by Chiodi et al.10 These workers found that breathing small concentrations of CO produced slight elevation in arterial carbon dioxide pressure (PaCO2), but left the arterial oxygen pressure (PaO2) essentially within normal limits. The differences between the rabbit's response to low O2 mixtures and CO might thus depend on differences in ventilation, PaCO2 and PaO2. The effects of PaCO2 and ventilation on cardiac output and heart rate were excluded by the experiments of Korner and Edwards,3 who showed that little effect was observed when PaCO2 was elevated in the presence of a normal or elevated PaO2; however, in the presence of a low PaO2 elevating the PaCO2 produced bradycardia and reduction in cardiac output. This response differs considerably from the effects with CO. The difference in the arterial oxygen tension in the two types of hypoxia thus appears to be an important factor in accounting for the difference in the circulatory response of the rabbit to low O2 mixtures and CO. A comparison of the circulatory effects in these two types of hypoxia thus offers the possibility of assessing the role of the PaO2 in various aspects of circulatory regulation in the intact, unanesthetized rabbit.

The renal blood flow accounts for a large...
fraction of the resting cardiac output and might be expected to play a part in the circulatory adjustments to low O₂ mixtures and carbon monoxide. In moderate arterial hypoxia in man and the dog only minor changes in renal blood flow (RBF) and glomerular filtration rate (GFR) have been observed, but in severe arterial hypoxia the RBF and GFR were markedly reduced. In asphyxia marked reductions in RBF have been described in the anesthetized rabbit and in diving mammals. The effects of CO on the renal circulation have not been investigated. However, in anemia the reduced O₂-carrying capacity of the blood leads to the development of a somewhat similar type of “tissue” hypoxia with an essentially normal Pao₂. The changes in the renal circulation reported in anemia have been variable, probably as a result of differences in the types of anemia studied and due to uncertainty regarding the renal PAH extraction ratio in anemia. The present study was therefore undertaken to determine the part played by changes in the renal circulation in the circulatory adjustments to low O₂ mixtures and to carbon monoxide in the unanesthetized rabbit, and to investigate which components of the renal vascular response were under direct nervous control.

**Methods**

The experiments were carried out on 91 hutch bred male rabbits of mixed breed varying in weight from 1.5 to 3.5 kg. Details of operative, experimental and analytical procedures have been described elsewhere. In 50 animals all operative procedures were carried out using local anesthesia. In 35 rabbits where renal vein catheterization was carried out, and in 25 animals subjected to bilateral ureteric catheterization, the preliminary operative procedures were carried out using light sodium thiopental anesthesia. In the latter two groups the determination of renal clearances, cardiac output, etc. commenced about four hours after recovery from anesthesia. There was no obvious difference in the response of these animals to the various inspired gas mixtures when compared to completely unanesthetized animals.

The general plan of the experiment was, except where stated otherwise, as shown in figure 1. All clearance determinations during control and “treatment” periods were carried out during moderate water and mannitol diuresis as described previously. Following the control observations the animals breathed one of the following inspired “treatment” mixtures: 21% O₂ in N₂; 0.1% CO + 21% O₂ in N₂; 0.2% CO + 21% O₂ in N₂. The gases were passed through rotameters at appropriate flow rates, and the mixtures were stored in a 100-liter Douglas bag. The animals breathed the mixtures through a respiratory valve from a very light polythene bag, as described.

Results in brackets represent mean from 4 animals breathing 9.6% O2, omitting results from 1 animal where extraction ratio fell by 19%.

4 animals only in each group.

Treatment effect statistically significant. \((P < 0.05)\)

RENAL CIRCULATION IN HYPOXIA

Preceding 1.29 inspired oxygen concentration \((\text{FiO}_2)\) was measured with a Beckman model E2 O2 analyzer, and carbon monoxide \((\text{FiCO})\) was measured with an Infra Red Development Co. CO analyzer. In about half the experiments where the inspired treatment mixture was 9.6% \(\text{O}_2\) a period of breathing 11.5% \(\text{O}_2\) in \(\text{N}_2\) for 30 minutes preceded the change to 9.6% \(\text{O}_2\), since it had been shown previously that the animals tolerated the latter mixture better in this way. However on this occasion there was no significant difference in response in the "acute" 9.6% \(\text{O}_2\) group and the "gradual induction" 9.6% \(\text{O}_2\) group and the results from both groups have accordingly been pooled.

NOTATION IN CARBON MONOXIDE AND LOW \(\text{O}_2\) EXPERIMENTS

Since the presence of carboxyhemoglobin profoundly alters the oxyhemoglobin dissociation curve,4-8 the symbol \(\text{S'o}\) with appropriate suffix is used to denote the ratio of \((\text{O}_2\text{Hb})/(\text{COHb} + \text{HbO}_2 + \text{Hb})\) in the blood, in the presence of significant amounts of carboxyhemoglobin. Thus \(\text{S'0}\) refers to the arterial \((\text{O}_2\text{Hb})/(\text{total Hb})\) ratio in the presence of carboxyhemoglobin, and \(\text{S'a}_0\) refers to arterial \(\text{O}_2\) saturation in the absence of carboxyhemoglobin.

Results

EFFECT OF BREATHING 9.6% \(\text{O}_2\) AND 0.2% CO ON RENAL PAH EXTRACTION RATIO

Renal vein catheterization was carried out in 36 animals. Each animal breathed room air during the control period. During the subsequent treatment period five animals breathed 21% \(\text{O}_2\), five animals breathed 9.6% \(\text{O}_2\) and six animals breathed 0.2% \(\text{CO}\). The results in table 1 show that the effect on the renal PAH extraction ratio of breathing low \(\text{O}_2\) mixtures was small and barely significant. In these experiments there was significant reduction in renal vein \(\text{S'o}\) (or \(\text{S'a}_0\)) in the CO experiments, indicating that there was probably significant reduction in the renal \(\text{P'O}_2\) in both experiments. The results show that the use of uncorrected PAH clearances when breathing 9.6% \(\text{O}_2\) or 0.2% \(\text{CO}\) will result in negligible errors when equating these clearances with true renal plasma flow \((\text{RPF})\). Reduction in the renal \(\text{O}_2\) consumption occurred in the experiments with 9.6% \(\text{O}_2\) and 0.2% \(\text{CO}\) only when there was a reduction of more than 30% in the RBF.

EFFECT OF BREATHING 9.6% \(\text{O}_2\)

Following control observations with all animals breathing room air, 24 animals breathed 9.6% \(\text{O}_2\) during the treatment period (fig. 1), and 12 animals breathed 21% \(\text{O}_2\). There was a considerable increase in respiratory minute
FIGURE 2
SaO₂ (or S’(O2)) in relation to the change in ventilation, expressed as percentage of each animal's own control value (upper panels), and the Right Atrial SaO₂ (or S’(O2)) (lower panels). volume (upper left panel fig. 2). Although the animals breathed a gas mixture of approximately constant composition the magnitude of the respiratory response varied between individual animals. The range of SaO₂ values varied from 84% to 46%, reflecting variation in ventilation:perfusion ratios between different animals. The right atrial SaO₂ was reduced below normal values whilst breathing 9.6% O₂. In the 24 animals breathing 9.6% O₂ during the treatment period the O₂ consumption was 23.7 ml/min STPD when breathing room air, and 30.9 ml/min STPD when breathing the low O₂ mixture (difference 2.8 ± 0.85 (SE) ml/min). In the 12 animals breathing 21% O₂ during the treatment period corresponding values for SaO₂ were 25.6 ml/min STPD while breathing room air, and 24.8 ml/min STPD whilst breathing 21% O₂ (difference 0.8 ± 1.5 (SE) ml/min).

The effect of arterial hypoxia on the urine flow was variable. The mean urine flow whilst breathing room air was 0.72 ml/min and 0.50 ml/min whilst breathing 9.6% O₂.

The changes in cardiac output and RBF are shown in figure 3. In the present experiments the proportion of animals showing an increased cardiac output while breathing low...
RENAL CIRCULATION IN HYPOXIA

O₂ mixtures was greater than observed previously, possibly as a result of further reduction in the amount of handling and excitement to which the animals were subjected. The heart rate at the time of the clearance determinations in animals breathing 9.6% O₂ was 93.5 ± 2.9 (SE) % of the control value (taken as 100%). There was no significant change in arterial pressure with increasing hypoxia. There was reduction in RBF related to the degree of severity of hypoxia (fig. 3). Although the GFR was also reduced, the effect was smaller than the effect on the RPF and there was thus an increase in filtration fraction at low Sa O₂ values. The results indicate that there was an overall increase in the renal vascular resistance with a selective increase in postglomerular resistance with increasing severity of hypoxia.

EFFECT OF BREATHING 0.1 AND 0.2% CO

Twenty-seven animals breathed 0.1 or 0.2% CO during the treatment period. There was a small, but statistically significant increase in respiratory minute volume. The percentage of carboxyhemoglobin varied between 30% and 58% depending on the concentration of inspired CO. The mixed venous S'K was reduced in relation to the reduction in arterial O₂-carrying capacity (fig. 2). The O₂ consumption was 26.4 ml/min STPD while breathing room air, and 22.9 ml/min STPD when breathing CO mixtures (difference 3.5 ± 0.60 (SE) ml/min).

There was usually some reduction in urine flow in the course of breathing CO mixtures, the urine flow of the group being 0.60 ml/min while breathing room air and 0.37 ml/min while breathing CO.

Figure 4 shows that the cardiac output increased in relation to the reduction in S'a_o. The mean heart rate while breathing carbon monoxide was 112.9 ± 24.65% (se) of the control value and tachycardia was observed in most animals. There was reduction in car artery pressure, RBF and GFR, each variable being reduced by approximately 20%. The GFR and RPF were reduced to approximately the same degree, so that there was no significant change in filtration fraction with reduction in S'a_o. There was no significant effect in the group on the renal vascular resistance.

The fall in arterial pressure, RBF and GFR, did not appear to be closely related to the degree of reduction in arterial O₂-carry-

*Significantly different from control value (P < 0.05)
+Significantly different from first treatment value (P < 0.05)

The results indicate that the degree of reduction in the arterial pressure was significantly greater when breathing 0.2% CO compared to 0.1% CO. There was no significant additional effect on the RBF and GFR in these animals when breathing 0.2% CO. The maintenance of constant RBF and GFR with 0.2% CO despite an additional fall in blood pressure suggests the occurrence of some renal vasodilatation with this gas mixture.

COMPARISON OF EFFECTS OF 9.6% O₂ WITH CARBON MONOXIDE

There was a significantly larger effect on the respiratory minute volume in animals breathing 9.6% O₂. In the range of SₐO₂ values of 50% to 70% the respiratory minute volume was 198 ± 13.5 (se) per cent of control with 9.6% O₂. In animals breathing 0.1 or 0.2% CO with values of SₐO₂ in the range of 50% to 70% the increase in ventilation was 116 ± 5.4 (se) per cent of the control value, the difference being statistically significant. In contrast to the immediate maximal respiratory response with 9.6% O₂ the ventilation increased more slowly and gradually in animals breathing CO. The large increase in ventilation with 9.6% O₂ suggests a reduction in PₐO₂, in agreement with previous observations in the rabbit. In the present experiments measurements of PₐO₂ and pH were not carried out and only approximate estimates of oxygen pressures in mixed venous blood of the PₐV o₂ can therefore be made from the data shown in figure 2. In animals breathing 9.6% O₂ the SₐO₂ (right atrial) varied from 50% to 18%. Using the rabbit's oxyhemoglobin dissociation curve and assuming a PₐO₂ of 15 mm Hg and body temperature of 40°C (normal rabbit body temperature), the estimated range of PₑO₂ in the CO experiments may be estimated as ranging from 30 to 11 mm Hg. It seems reasonable to infer considerable overlap in PₑO₂ even though the PₑO₂ probably varied widely between animals even when breathing a given treatment mixture.

The cardiac output increased to approxi-
RENAL CIRCULATION IN HYPOXIA

Nearly the same degree with 9.6% O₂ as with
CO for a given value of SaO₂ or S'ao₂, but
there were significant differences in the re-
sponse of the heart rate of the two groups.

The RBF was reduced to a greater extent
in animals breathing 9.6% O₂ than in those
breathing CO despite the fact that the blood
pressure remained unchanged in the former
group, but was reduced in the latter. This
suggests that renal vasoconstriction occurs
with 9.6% O₂. The difference in the renal vas-
cular response between low O₂ mixtures and
CO can be demonstrated more clearly by ob-
serving the response to both mixtures in a
given animal (table 2, Group C). Figure 5
shows that when a rabbit breathed 9.2% CO
the arterial and mixed venous O₂ content were
reduced. There was increase in cardiac out-
put, some increase in ventilation, and reduc-
tion in arterial pressure, RBF and GFR. When
the inspired gas was changed to 9.8%
O₂ further increase in ventilation occurred.
The O₂ content of the arterial and mixed ve-
nous blood increased slightly. The blood pres-
sure increased from its previous level, but
despite this there was further significant re-
duction in RBF, clearly indicating the occur-
rence of renal vasoconstriction. This effect
was observed in all four animals tested in this
way and is in agreement with the results ob-
served in the main groups shown in figures
3 and 4.

THE ROLE OF THE RENAL VASOMOTOR
NERVES IN THE RESPONSE TO 9.6% O₂

Whilst the above experiments demonstrate
the occurrence of renal vasoconstriction in
animals breathing 9.6% O₂, they do not indi-
cate the mechanism involved. Vasoconstriction
could be due to increased sympathetic con-
strictor tone, or due to the liberation of hu-
moral agents such as epinephrine. The part
played by the renal vasomotor nerves was
studied in 14 animals where separate clear-
ance estimations for each kidney were carried
out. In seven of these the left kidney was
denervated six to eight days before an experi-
ment.

Figure 6 shows the effects of 9.6% O₂ on

![Graph showing effects of breathing 0.2% CO and 9.8% O₂ on various parameters.

The graph shows that breathing 0.2% CO reduces arterial and mixed venous O₂ content, increases cardiac output, and decreases arterial blood pressure, RBF, and GFR. Breathing 9.8% O₂ causes further increase in ventilation and an increase in arterial O₂ content and mixed venous O₂ content.

In animals with both kidneys innervated, the RBF was reduced to a greater extent in the innervated kidney when breathing 9.6% O₂ than in the denervated kidney. On resuming air breathing the RBF increased in the innervated kidney, but there was little change in flow to the denervated kidney. Breathing 8% O₂ again resulted in a marked difference between the two sides. The results of all experiments are summarized in figure 7. In animals with both kidneys in-
Experiment showing effect of breathing 9.6% O₂ and 8% O₂ on cardiac output, arterial pressure, RBF and GFR in rabbit with chronic denervation of left kidney. Separate clearance determinations were carried out from each kidney. White—breathing room air. Black—breathing low O₂ mixture.

In nerveated the response was similar on both sides. However, in animals with one kidney denervated there was relatively little change in RBF on the denervated side with increasing severity of hypoxia, but a marked reduction in RBF on the innervated side. The experiments demonstrate the importance of the renal vasomotor nerves in the production of renal vasoconstriction with low oxygen mixtures. The effect on the GFR was similar to the effect on the RBF in these experiments (fig. 7) and it is thus likely that the vasoconstrictor nerves terminate near the afferent arteriole. Figure 7 shows that there was no difference in filtration fraction on innervated and denervated sides, and the increase in filtration fraction with reduction in SₐO₂ (figs. 3 and 7) is thus not the result of direct nervous action on the renal blood vessels.

Because of variation in the renal vascular response between animals it is not obvious from the results in figure 7 if there is a threshold for the occurrence of renal vasoconstriction. The effects of a number of different low O₂ mixtures were studied in greater detail in two animals, and the result of one experiment...
RENAL CIRCULATION IN HYPOXIA

369

Experiment showing effect of breathing different inspired gas mixtures on RBF and GFR in innervated kidney and chronically denervated kidney of an unanesthetized rabbit. The renal measurements are the average of two clearance periods for each inspired gas mixture.

is shown in figure 8. There was no difference in the behaviour of RBF and GFR on innervated and denervated sides when the animal breathed 11.8% O\textsubscript{2} (Sa\textsubscript{O\textsubscript{2}} 85%). A small degree of vasoconstriction could be demonstrated on the innervated side when breathing 10.4% O\textsubscript{2} and 9.6% O\textsubscript{2} (Sa\textsubscript{O\textsubscript{2}} 79% and 77% respectively), and this became marked with increasing severity of hypoxia. This result demonstrates that renal vasoconstriction requires the presence of a more severe degree of arterial hypoxia than is required to bring about an increase in ventilation.

In order to further investigate the relationship of the Pa\textsubscript{O\textsubscript{2}} to renal vasoconstriction, bilateral denervation of the carotid and depressor nerves was carried out in two animals in two stages, eight days before the experiment. Figure 9 shows the result of one experiment. The animals were not able to tolerate 9.6% O\textsubscript{2} and higher inspired O\textsubscript{2} pressures were used. The ear artery pressure was 103 mm Hg preceding the test period and was 114 mm Hg in the other animal. These values are lower than might be expected following complete baroreceptor denervation. It is possible that baroreceptor denervation may not have been complete, or the prolonged period of rest in the experimental cage following the operative procedures may have reduced the blood pressure. Chemoreceptor denervation was probably adequate as judged by the very small increase in ventilation with very severe
FIGURE 10
Experiment showing effect of breathing 0.2% CO in 21% O₂ and 8% O₂ in N₂ on cardiac output, arterial pressure, RBF and GFR on rabbit with chronic denervation of left kidney. Separate clearance measurements were carried out from each kidney. White—breathing room air; stippled—breathing 0.2% CO in 21% O₂; black—breathing 8% O₂.

hypoxia (SaO₂ 47%). The renal vascular response differed considerably from the response produced normally by this degree of hypoxia. The degree of reduction in RBF was much smaller than usual, and it appeared to be related to the reduction in blood pressure. There was a fall in renal vascular resistance instead of the usual rise. The results suggest that the arterial chemoreceptors are normally of importance in the renal vasoconstriction of arterial hypoxia.

THE ROLE OF THE RENAL VASOMOTOR NERVES IN THE RESPONSE TO 0.2% CO

This was investigated in nine animals, in five of which left renal denervation had been carried out. There was much less difference in the response between innervated and denervated kidney with CO than with 9.6% O₂ (fig. 10). In all animals there was a slightly greater reduction in RBF (table 3) and GFR on the innervated side during the first 10 to 20 minutes of breathing CO. During steady state conditions, however, there was no difference in behaviour between the two sides. In all animals the characteristic constriction response to low O₂ mixtures was demonstrated at the end of the experiment (fig. 10). The part played by the renal vasomotor nerves in the reduction in RBF and GFR in the CO experiments thus appears to be small.

Figure 10 shows that the maximum fall in RBF occurred in both innervated and denervated kidney during the initial fall in blood pressure. Subsequently there was no change or a slight increase in RBF despite further fall in arterial pressure. This suggests the occurrence of some renal vasodilatation with 0.2% CO.

Discussion

The experiments demonstrated significant differences in the response of the renal circulation of the rabbit following exposure to low oxygen mixtures and to carbon monoxide. The mean reduction in RBF was greater in animals breathing 9.6% O₂ than in those breathing the carbon monoxide and occurred as a result of renal vasoconstriction. The renal vasomotor nerves constricting the afferent arteriole played an important part in this response. The physiological evidence regarding the site of action is in accord with anatomical demonstration by Mitchell that the afferent arteriole is more richly innervated than the post-glomerular vessels. Increased nervous vasoconstriction did not however account for the increased filtration fraction observed in animals with the most severe degrees of hypoxia. A similar increase in filtration fraction can be produced by infusions of epinephrine.
and norepinephrine. Since these substances are known to be liberated in severe hypoxia it is possible that they may have played a part in the post-glomerular constriction in the rabbit, but the present experiments provide no proof of this. It appears that more severe reduction in \( P_{O_2} \) is required to bring about renal vasoconstriction, than is required to produce an increase in ventilation, and that the filtration fraction increases only during the most severe degrees of hypoxia.

Denervation of the carotid sinus region and of the depressor nerve was carried out in two animals and in both of these reduction in renal vascular resistance with relatively slight effects on renal blood flow was observed in place of the usual constrictor response. The renal vasoconstriction which occurs in the innervated kidney of the rabbit breathing 9.6% \( O_2 \) would thus appear to be reflexly mediated with excitation of the carotid and aortic chemoreceptors initiating the reflex.

In contrast to the results with low \( O_2 \) mixtures there was no evidence of reduction in RBF due to nervous constriction during the steady state in the CO experiments and the response appeared to be partly passive due to fall in blood pressure, and partly the result of local renal dilatation. The passive reduction in RBF due to the fall in arterial pressure is consistent with the results of pressure-flow studies in the isolated kidney.

Transient and slight renal vasoconstriction occurred in the initial period of breathing CO, at the time of the steepest fall in blood pressure and it is possible that this may have been of baroreceptor origin, though the present experiments provide no proof of this. The experiments were not designed to test the role of catechol amines (whose liberation might be expected in relation to the fall in blood pressure from the experiments of Heymans and Neil, and Tournade and Chabrol, cited in refs. 35) in the response to CO mixtures.

In addition to the differences in the renal vascular response there were significant differences in ventilation, heart rate, and blood pressure in the response of the rabbit to low \( O_2 \) mixtures and CO, in agreement with previous findings. In these two types of hypoxia differences in \( P_{O_2} \), \( P_{CO_2} \), blood pH and possibly direct tissue effects (in the case of CO) might be expected to contribute to the difference in circulatory response. The results suggest that differences in \( P_{O_2} \) probably do not account for the different responses since there was considerable overlap in the estimated \( P_{O_2} \) in both types of hypoxia. Similarly direct interference with tissue oxygen transport by CO is unlikely since the changes observed in total and renal oxygen consumption were very similar with CO and low \( O_2 \) mixtures. Changes in blood pH were not measured and are likely to be different in the

dications that differences in \( P_{O_2} \) probably do not account for the different responses since there was considerable overlap in the estimated \( P_{O_2} \) in both types of hypoxia. Similarly direct interference with tissue oxygen transport by CO is unlikely since the changes observed in total and renal oxygen consumption were very similar with CO and low \( O_2 \) mixtures. Changes in blood pH were not measured and are likely to be different in the
two types of experiments, with a respiratory alkalosis in the low O₂ experiments and a mild respiratory acidosis in the CO experiments.

Previous experiments in the rabbit have shown that increasing the ventilation by increasing the Paco₂ in the presence of a normal or elevated PaO₂ had no significant effect on cardiac output and heart rate during the steady state. Increasing the Paco₂ when breathing low O₂ mixtures resulted in more marked reduction in cardiac output and bradycardia than occurred with low O₂ mixtures alone, thus differing from the response to carbon monoxide. It therefore seems unlikely that the differences in arterial Paco₂ account for the differences in response to low O₂ mixtures and CO. The difference in Paco₂ in the two types of experiments appears to be a major contributing cause for the different responses. The CO experiments showed a smaller increase in respiratory minute volume, a finding consistent with the view that with this gas mixture there was less stimulation of the arterial chemoreceptors than with low O₂ mixtures. This is supported by the direct observations of Duke et al. and Joels and Neil, who showed that concentrations of COHb in excess of those used in the present experiment were without effect on carotid body discharge rates. The demonstration in the present experiments that the renal response to low O₂ mixtures becomes rather similar to the response to CO mixtures after chemoreceptor denervation also suggests that differences in Paco₂ acting via the arterial chemoreceptors account for the different responses to low O₂ mixtures.

In summary, the effects of breathing 9.6% O₂ in N₂ and of breathing 0.1% to 0.2% CO in air on the renal blood flow (RBF), glomerular filtration rate (GFR), and renal PAH extraction ratio were studied in the unanesthetized rabbit in relation to changes in cardiac output, heart rate, blood pressure, and ventilation. All experiments were carried out during moderate water and mannitol diuresis. The RBF and GFR were reduced in both types of hypoxia but this effect was produced by different mechanisms. With low O₂ mixtures reduction in RBF and GFR occurred mainly as a result of nervous vasoconstriction acting on the afferent arteriole. The arterial chemoreceptors played a part in the production of vasoconstriction. With carbon monoxide, reduction in RBF and GFR occurred mainly as a result of passive reduction in blood pressure, and only slight transient nervous vasoconstriction could be demonstrated in the early period of exposure to this gas. The results suggest that differences in arterial oxygen tension (PaO₂) were of major importance in accounting for the differences in renal circulatory effects of low O₂ mixtures and CO in the rabbit.
