A New Role of Mister (MR) T in Hypertension
Mineralocorticoid Receptor, Immune System, and Hypertension

Natalia R. Barbaro, Annet Kirabo, David G. Harrison

Emerging evidence has shown that inflammation and immunity play a central role in the genesis of hypertension. Cells of the immune system, including macrophages and T cells, have been observed in tissues of humans with hypertension and experimental evidence dating to the 1960s has suggested that both the elevation in blood pressure and end-organ damage are in part mediated by this immune cell infiltration. Studies in the past decade have shown that mice lacking T cells are protected against both angiotensin II and salt-sensitive hypertension and that adoptive transfer of T cells restores blood pressure in these animals. The T cells that accumulate in kidneys and vessels release inflammatory cytokines, including interleukin 17A, tumor necrosis factor-α, and interferon-γ (IFN-γ), that promote vascular dysfunction and renal damage.1 Macrophages and dendritic cells in tissues also release cytokines and metalloproteinases. These powerful signals affect vascular function by promoting vasoconstriction, remodeling, and fibrosis, and in the kidney, locally released cytokines alter renal tubular sodium reabsorption and antagonize pressure natriuresis.

Article, see p 1584

There is interest in the subsets of immune cells contributing to hypertension, with evidence supporting roles of CD8+ T cells, T17 CD4+ T cells, B cells, monocytes, and monocyte-derived dendritic cells. Studies in mice and humans have emphasized a role of CD8+ T cells in hypertension, as these cells seem to be major sources of IFN-γ and an oligoclonal population of these cells accumulates in the kidney of hypertensive mice. Moreover, CD8−/− mice are partially protected against angiotensin II- and DOCA-salt–induced hypertension, whereas CD4−/− mice are not.2 There is an increased number of circulating senescent CD8+ T cells in humans with hypertension that produce IFN-γ, tumor necrosis factor-α, granzyme B and perforin and this is accompanied by a striking increase in plasma levels of C-X-C type 3 receptor chemokines, which are tissue homing attractants for T cells.3 We have also observed an increase in IFN-γ-producing CD8+ T cells in humans with hypertension.4

Classically, T cells require 3 signals for activation, referred to as signals 1, 2, and 3 (Figure). Signal 1 is T-cell receptor recognition of specific antigenic peptides presented in the context of class I or class II major histocompatibility complexes on antigen-presenting cells. Signal 2 is costimulation, involving interactions of ligands like CD80 and CD86 on antigen-presenting cells with CD28 on T cells. These 2 interactions occur within the immunologic synapse, where they are accompanied by other modulating receptor–ligand interactions between the antigen-presenting cell and the T cell. Signals 1 and 2 are sufficient to promote T-cell proliferation, cytokine production, and often mobilization from secondary lymphoid organs. Signal 3, on the contrary, involves stimulation of accessory receptors outside of the immunologic synapse by hormones, cytokines, and danger signals present in the inflammatory milieu. Some of these are released by the antigen-presenting cell, whereas others are derived from nearby stromal cells or from the circulation. Thus, cytokines like interleukin (IL)-12, IL-4, IL-1b, IL-23, and transforming growth factor-β skew T cells to T1, T2, Th17, and regulatory phenotypes by activating transcriptional pathways and epigenetic alterations that are still being elucidated. It was previously thought that these commitments were irreversible, but there is ample evidence of plasticity of T-cell phenotype and that some cells can serve >1 function.

In this issue of Circulation Research, Sun et al5 provide us with a new signal 3 that has relevance to immune activation in hypertension. The authors provide evidence that the mineralocorticoid receptor (MR) in T cells, and particularly in CD8+ T cells, modulates their production of IFN-γ and ultimately promotes hypertension. To accomplish this, the authors used Cre-Lox technology to eliminate the MR in all T cells, while leaving it intact in all other cells. Surprisingly, the resultant mice (TMRKO mice) demonstrated blunted hypertension, attenuated fibrosis in the aorta and kidneys, reduced albuminuria, and preserved endothelium-dependent vasodilatation on chronic infusion of ang II. The authors showed by flow cytometry that both CD4+ IFN-γ+ T and CD8+ IFN-γ+ T cells are reduced in kidneys and aorta of hypertensive TMRKO mice. In further experiments, they found that MR mediates production of IFN-γ by CD8 T cells. MR deletion reduced CD8+ IFN-γ+ CD8+ T cells, whereas overexpression of MR using a lentivirus markedly increased production of IFN-γ by CD8+ T cells compared with cells infected by a control lentivirus. Moreover, Sun et al6 used chromatin immunoprecipitation assays to identify nuclear factor of activated T cell 1 and activator protein-1 binding to specific regions of the IFN-γ gene promoter and confirmed interactions between MR and nuclear factor of activated T cell 1 and between the MR and...
the activator protein-1 subunits c-Fos and c-Jun. In addition, mice engineered to overexpress MR in T cells had exacerbated hypertensive responses to Ang II. Treatment with anti–IFN-γ-neutralizing antibodies during ang II infusion prevented hypertension in wild-type and TMRKO mice confirming that T-cell MR overexpression exacerbates Ang II–induced hypertension through IFN-γ.

Classical teaching indicates that the major action of aldosterone and the MR is to promote renal sodium reabsorption, largely by increasing abundance of the epithelial sodium channel on the apical membrane of epithelial cells in the distal nephron. Although this is likely its major role, there is increasing evidence that aldosterone can act on the MR in other cells to promote hypertension. Of note, McCurley et al.6 showed that specific deletion of MR in the vascular smooth muscle blunted age-related elevations in blood pressure, vascular myogenic tone, and fibrosis. The endothelial MR receptor contributes to the vascular stiffening and dysfunction that accompanies obesity.7 Related to the present study of Sun et al.,5 there is also evidence that MR receptors on macrophages and dendritic cells affect their phenotype and cytokine production.8

This current study adds to our understanding of the role of IFN-γ in hypertension. Although some studies have shown a protective or neutral effect of this cytokine,9 others have supported its role in hypertension. As an example, we have shown that IFN-γ−/− mice exhibit a blunted rise in blood pressure in response to ang II infusion and that the antidiuretic and antinatriuretic response of ang II is virtually absent in these animals.10 This effect, in part, seems to be related to changes in the sodium-hydrogen exchanger 3 in the proximal nephron, which modulates pressure natriuresis.10 Sun et al.5 observed an increase in T cells in the kidney in ang II–induced hypertension. In keeping with this, we have observed accumulation of memory T cells in the kidney and vasculature in hypertensive mice that the effector memory subset of T cells are a major source of IFN-γ in the kidney of hypertensive mice.11

An interesting finding made by Sun et al.5 is that immunoclearing of IFN-γ more effectively lowered blood pressure than did knockout of the MR in T cells. This is almost certainly because there are factors in addition to the MR, such as the transcription factor Tbet and JAK/STAT signaling that regulate IFN-γ production. Nevertheless, it is therapeutically possible to block the MR with currently available, commonly used drugs. In this regard, MR antagonists have emerged as highly effective and likely indispensable agents to treat resistant hypertension. A recent randomized, double-blind clinical trial showed that spironolactone is superior to either α-1 or β-adrenergic receptor blockade as an add-on drug in the treatment of such patients, supporting a predominant role of MR activation in the pathophysiology of resistant hypertension.12 It is also possible that the mechanism proposed by Sun et al.5 has relevance to heart failure, where T cells have been identified to play a pathogenic role,13 and MR receptor blockade clearly improves outcome. Thus, the findings by Sun et al.5 suggest a previously unknown anti-inflammatory role of MR blocking agents that might explain some of their striking therapeutic benefits beyond the simple diuretic effects of these drugs.
