Hemodynamic Variables Affecting the Relation
Between Mean Left Atrial and Left
Ventricular End-Diastolic Pressures

By Andrew G. Wallace, M.D., Jere H. Mitchell, M.D., N. Sheldon
Skinner, Jr., M.D., and Stanley J. Sarnoff, M.D.

Changes of pressure in the atrium have
two direct and important circulatory conse-
quences. The first is that a change of mean
atrial pressure alters the central pressure
level which must be exceeded by blood return-
ning from the venous system. The second is
that a change of atrial pressure will influence
the rate of ventricular filling and ventricular
end-diastolic pressure. The significance of
the latter is that this value is known to exert
important effects on the stroke work and
stroke power of the ventricle and thus influ-
ence the forward propulsion of blood. Those
factors which determine the level of mean
atrial pressure for any given level of ventric-
ular end-diastolic pressure achieved are,
therefore, of importance for an increased
understanding of total circulatory integra-
tion.

Previous studies have shown that autonomic
nerve stimulation can change substantially
the relation between mean left atrial pressure
(MLAP) and left ventricular end-diastolic
pressure (LVEDP). The objectives of this
communication are first to present data from
experiments in which this relation (MLAP—
LVEDP) was examined while aortic pressure,
stroke volume, and heart rate were each var-
ied independently. Second, experiments will
also be described to make clear the importance
of sympathetic nerve activity in keeping this
relation within narrow limits when tachycard-
dia occurs. A preliminary report of these ob-
servations has appeared elsewhere.

Methods

Mongrel dogs weighing 16 to 28 kg were anesthe-
tized with a warmed mixture of chlороaloce (60
mg/kg) and urethane (600 mg/kg) given intraven-
ously. Congestion was prevented by an initial
intravenous dose of 75 mg of heparin followed by
doses of 10 mg given hourly. Respiration was
maintained by a Starling pump.

Two preparations were used. The first is illus-
trated in figure 1. Total aortic flow (cardiac output
minus coronary flow) was led through a bypass
placed in the descending thoracic aorta and mea-
sured with a Potter electroturbinometer (Pet.).
After cannulation of the carotid arteries the bra-
chiocephalic artery was ligated and the head was
perfused from the bypass, distal to the flow meter.
Aortic flow could be controlled or varied by means
of a pump-operated arteriovenous shunt (AVS)
between the aortic bypass and the inferior
vena cava (IVC). Aortic pressure was measured
through a large bore metal sound introduced into
the left subclavian artery and mean aortic pres-
sure was controlled by connecting a large reservoir
(Pressure bottle) to the aortic line and keeping a
constant air pressure, equal to the desired mean
aortic pressure, over the blood. The heart was
paced from the right atrium (RA) with a Grass
impulse generator. Left atrial (LA) and left ven-
tricular (LV) pressures were measured through
wide-bore sounds introduced through the atrial
appendage and apical dimple, respectively, and
connected to Statham strain gauge transducers
(Tr.). The right stellate ganglion was resected; the
left stellate was isolated by cutting all central rami
and placed in a bipolar stimulating electrode. Bi-
lateral cervical vagotomy was performed in all
animals. In all studies other than those concerning
the effects of stellate ganglion stimulation, reflex
activity was diminished by a dose of mecamyl-
amine (Inversine), 10 to 20 mg/kg, sufficient to
abolish the pressor response to bilateral carotid
artery occlusion.

The second preparation has been described in
detail elsewhere. It consisted of a right heart
bypass in which all venous blood was led from the
right heart to a reservoir and then pumped through

261
FIGURE 1
Schema for arteriovenous fistula preparation in which cardiac output, mean aortic pressure, and heart rate could be varied independently. Abbreviations defined in text.

A flow meter, bubble trap and heat exchanger back into the cannulated main pulmonary artery. Total cardiac input could be controlled by adjusting pump rate. The heart was electrically paced from the right atrium. Aortic pressure was controlled by a variable resistance on the descending aorta. Reflex activity was abolished by bilateral cervical vagotomy plus pharmacologic ganglionic blockade with mecamylamine. Aortic, left atrial, and left ventricular pressures were measured as indicated in the first preparation. Zero baseline for the left ventricular and left atrial pressure gauges was the level of the tip of the recording sound within the ventricle.

Results
A) EFFECT OF CHANGING AORTIC PRESSURE
Ten experiments were performed on six animals in which the effect of changing mean aortic pressure on the MLAP—LVEDP relation was observed. In these experiments mean aortic pressure was varied over a maximal range of 50 to 160 mm Hg while stroke volume and heart rate were maintained constant. Increasing or decreasing mean aortic pressure did not modify the MLAP—LVEDP relation in any of these animals. The experiments are summarized in table 1 and one such study is graphed in figure 2A.

B) EFFECT OF CHANGING STROKE VOLUME
The influence of changing stroke volume on the MLAP—LVEDP relation was investigated in eight animals. Heart rate and mean aortic pressure were each held constant while cardiac output was augmented. Stroke volume was changed over a maximal range of 5 to 46 ml with no consistent effect on the MLAP—LVEDP relation. One such study is graphed in figure 2B and data from 10 experiments are summarized in table 1.

C) EFFECT OF CHANGING HEART RATE
The influence of changing heart rate on the MLAP—LVEDP relation was examined in seven animals at constant mean aortic pressure and stroke volume. As seen in table 1 heart rate could be changed over a wide range with little or no effect on this relation. In nearly all animals, however, MLAP increased in relation to LVEDP at the higher rates studied. One such experiment is graphed in figure 3. Heart rate was increased from 120 to 150 beats/min with essentially no change in the MLAP—LVEDP relation, but as the rate was increased further MLAP—LVEDP rose. The increase of the MLAP—LVEDP relation at rapid rates was always the result of an elevation of MLAP with little change of LVEDP.

In all animals in which the MLAP—LVEDP relation increased, the heart rate at which this was observed coincided with the rate at which part or all of the atrial "A" wave occurred within the preceding ventricular beat. Figure 4 shows the effect of increasing heart rate on left atrial pressure and left ventricular diastolic pressure. Aortic pressure and stroke volume were constant. Ventricular end-diastolic pressure was only
1 cm H₂O higher at the rate of 222 than at 115. Mean atrial pressure, however, was 10 cm H₂O higher at the rate of 222 than at 115. Diastolic time between ventricular beats was reduced markedly at the rapid rate and the interval between atrial systole and ventricular systole (Aₚ-Vₚ interval) was prolonged from 58 msec at the rate of 115 to 120 msec at the rate of 222. Similar prolongation of the Aₚ-Vₚ interval was noted in all animals at the higher heart rates. The abbreviated ventricular diastole and the prolonged Aₚ-Vₚ interval both contributed to placing atrial systole largely within the period of the previous ventricular beat at the rapid rate.

D) EFFECT OF STELLATE GANGLION STIMULATION

The influence of stimulating the left stellate ganglion on the MLAP-LVEDP relation was investigated 29 times in 10 animals at constant mean aortic pressure and heart rate. In each experiment the effect was observed over a wide range of stroke volumes. In all animals, regardless of heart rate or stroke

volume, stellate ganglion stimulation decreased the MLAP—LVEDP relation. In any given animal stellate stimulation always produced a greater fall of the MLAP—LVEDP relation at rapid heart rates than at slow heart rates. In certain instances the effect of stellate stimulation was somewhat more prominent at high stroke volumes than at low stroke volumes, but this was not a consistent finding. The experiments illustrated in figure 5 are representative of the data. They show that as heart rate was increased from 131 to 221, stellate ganglion stimulation produced a greater fall of MLAP in relation to LVEDP.

In figure 6 the data from figure 5 are re-plotted by placing all the observations without stellate stimulation in the left panel (A) and all the observations during stellate stimulation in the right panel (B). Data obtained at a heart rate of 175 are also included. On the left, heart rate was increased from 131 to 175 with little effect on the MLAP—LVEDP relation. At rates of 206 and 221, however, MLAP was substantially higher for any given LVEDP. During stellate stimulation, heart rate was increased over the entire rate range from 131 to 221 with essentially no change in the MLAP—LVEDP relation.

WALLACE, MITCHELL, SKINNER, SARNOFF

Figure 7 shows tracings from an experiment which illustrates further the effects of stellate stimulation. In this experiment heart rate was held constant at 221 beats/min and mean aortic pressure at 70 mm Hg. In panel A, during the control period, LVEDP was 10 cm H$_2$O, MLAP was 12.5 cm H$_2$O, and cardiac output was 1850 ml/min. During stellate stimulation, panel B, cardiac output was 3350 ml/min, LVEDP was 10 cm H$_2$O and despite the markedly augmented cardiac output MLAP was only 5 cm H$_2$O. With stellate ganglion stimulation the duration of ventricular systole shortened from 195 msec to 160 msec and the A-V interval shortened from 90 msec to 60 msec. Both the longer diastolic interval and the shorter A-V interval enabled the atrium to contract after the mitral valve opened; before sympathetic stimulation the atrium clearly contracted prior to opening of the mitral valve.

**E) MEAN DIASTOLIC PRESSURE DIFFERENCE BETWEEN THE LEFT ATRIUM AND LEFT VENTRICLE DURING CHANGES OF HEART RATE AND STROKE VOLUME**

In nine animals the difference between mean pressures in the left atrium and left ventricle during diastole was measured under varying conditions of cardiac output and heart rate. This measurement was made by integrating the pressures in the two chambers from the "V" point of the atrial trace to onset of the subsequent ventricular contraction. In figure 8 two representative plots are shown relating the difference between the integrated pressures in the left atrium and ventricle to the average rate of flow across the mitral valve; the latter was calculated by dividing the stroke volume by the duration of the interval between the "V" point and the onset of left ventricular pressure rise. In panel A mitral valve flow rate was augmented by increasing stroke volume from 10.5 ml to 33.6 ml at a constant heart rate of 173. In panel B mitral valve flow rate was augmented by increasing heart rate from 120 to 220 at a constant stroke volume of 15 ml. While it is realized that the techniques of measurement do not make it possible to calculate mitral.

Circulation Research, Volume XIII, September 1963
valve resistance with a high degree of precision, nevertheless, in neither case did augmentation of mitral valve flow rate measurably influence the difference between mean pressures in the atrium and ventricle during filling. A corollary to this finding is that the elevated mean atrial pressure observed at rapid heart rates resulted from an increase of atrial pressure during ventricular systole, not during the diastolic filling period.

**Discussion**

The purpose of these experiments was to characterize the influence of several selected hemodynamic variables on the MLAP—LVEDP relation. Two preparations were used, each of which permitted independent control of stroke volume, aortic pressure, and heart rate. The results indicate that the MLAP—LVEDP relation is independent of stroke volume and of aortic pressure. Heart rate can be increased over a substantial range without influencing the MLAP—LVEDP relation. However, a critical rate exists in any given heart above which mean atrial pressure increases in relation to LVEDP. This increase results from an increase of MLAP with little or no change of LVEDP. Stellate ganglion stimulation decreases the MLAP—LVEDP relation at any given heart rate or stroke volume, and this effect is most prominent at rapid heart rates. The following factors were considered to be of importance in influencing the MLAP—LVEDP relation: the vigor of atrial systole, the timing of atrial systole, and the duration of ventricular diastole.

VIGOR OF ATRIAL SYSTOLE
Recent studies on the transport function of the atrium indicated that when the vigor of atrial systole was increased MLAP was lower for any given LVEDP and vice versa. The data reported in this paper concerning the effect of stellate ganglion stimulation are consistent with those observations and support the view that when atrial contractility is augmented the MLAP—LVEDP relation is reduced. In an investigation of the effect of stellate ganglion stimulation on atioventricular pressures, Ulmer and Randall stated that mean atrial pressure may increase, decrease, or show no change. In those experiments, however, cardiac output and heart rate were allowed to vary. In this study when heart rate and cardiac output were held constant stellate ganglion stimulation always reduced MLAP.

It has been shown that the MLAP—LVEDP relation is higher during atrial fibrillation than when an effective atrial systole occurs before each ventricular beat. This finding is consistent with the observation of Braunwald and Frahm who found that MLAP was higher in relation to LVEDP in a patient who developed atrial fibrillation during catheterization. Such findings during experimental and clinical atrial fibrillation support the
view that when the vigor of atrial systole is depressed MLAP is higher for any given LVEDP.\(^2\)

Wiggers and Katz demonstrated that the atrial contribution to ventricular filling was decreased by vagal stimulation and increased by epinephrine infusion.\(^5\) It has also been shown that direct cardiac sympathetic nerve stimulation can greatly augment the contribution made by the atrium.\(^6\) In addition, early in vitro studies suggested the possibility that the atrioventricular valve could be closed by atrial systole\(^11,12\) and Little reported convincing experiments in intact animals which demonstrated that the tricuspid valve could be closed solely as the result of atrial activity.\(^13\) Subsequent studies\(^14\) have shown that the mitral valve can be closed consequent to atrial contraction and relaxation, and that valve closure was dependent upon the vigor of atrial systole. These considerations suggest that atrial contraction can transport significant volumes of blood into the ventricle\(^2\) and close the mitral valve before the onset of ventricular systole.\(^14\) Both of these functions of the atrium provide a booster pump mechanism which tends to maintain a substantially lower mean atrial pressure for any LVEDP.

**TIMING OF ATRIAL SYSTOLE**

Gesell first noted that the interval between atrial and ventricular systole was of hemo-

dynamic significance.\(^15\) He showed, in dogs with heart block, that when atrial systole occurred at an optimal moment, arterial pressure was highest and venous pressure lowest. Wiggers and Katz\(^9\) and Jochim\(^16\) confirmed and extended many of the observations of Gesell. In view of the data presented in this report it would appear that a long \(A_s-V_s\) interval may influence the MLAP—LVEDP relation in the following manner. When part or all of atrial systole occurs against a closed mitral valve from the preceding ventricular beat, it contributes to an increase of mean left atrial pressure but fails to propel blood into the ventricle. When heart rate was increased in the absence of concomitant sympathetic nerve stimulation, atrioventricular conduction time \((A_s-V_s\) interval) lengthened. This observation is consistent with the conclusions of others\(^17\) that increasing heart rate prolongs atrioventricular transmission time. At rapid heart rates the long \(A_s-V_s\) interval and the short diastolic filling period both contributed to placing atrial systole within the period of the previous ventricular beat (fig. 4). Under these conditions the atrial contraction occurred against a closed mitral valve and increased MLAP. Stellate ganglion stimulation lengthened substantially the diastolic filling period and shortened the \(A_s-V_s\) interval\(^20\) (fig. 7). The net effect of sympathetic

Effect of changes in mitral valve flow rate on the difference between mean left atrial diastolic pressure and mean left ventricular diastolic pressure, L.A.p(mean)—L.V.p(mean). Panel A. Stroke volume increased at constant heart rate. Panel B. Heart rate increased at constant stroke volume.
stimulation was to reduce MLAP for any given LVEDP (fig. 5) and to extend markedly the range over which heart rate could be augmented with no change of the MLAP—LVEDP relation (fig. 6).

**DURATION OF VENTRICULAR DIASTOLE**

The experiments described in this report help to clarify the role of the diastolic filling period in determining the MLAP—LVEDP relation. At rapid heart rates, or at moderate rates with depressed ventricular performance, the duration of diastole may be very short and atrial systole may occur within the preceding ventricular beat. Under these conditions, slowing the heart rate or increasing ventricular contractility at a constant heart rate will lengthen the diastolic interval and permit atrial systole to occur after the mitral valve has opened. This mechanism was clearly an important factor at rapid rates, contributing to the decrease of MLAP—LVEDP by sympathetic stimulation. More rapid ventricular relaxation during sympathetic stimulation also may have contributed importantly to a longer diastolic period. The observation that the mean diastolic pressure difference between atrium and ventricle was not altered by changes of stroke volume or heart rate, suggests strongly that the normal mitral valve offers a negligible resistance to flow and, therefore, that the effect of changes of the diastolic interval on flow rate through the mitral valve is not of itself a critical factor affecting the MLAP—LVEDP relation.

**Summary**

The observations reported in this paper support the view that a vigorous and properly timed atrial contraction, by transporting blood into the ventricle and by approximating the atrioventricular valve prior to ventricular systole, provides a mechanism by which mean atrial pressure is maintained at a substantially lower level for any ventricular end-diastolic pressure than would be the case if these functions of the atrium were not operative. The central nervous system, by way of efferent sympathetic pathways, can regulate appropriately the vigor and timing of atrial systole as well as the duration of the diastolic filling period. The net effect of such regulation is to decrease mean atrial pressure at any given heart rate and cardiac output, and to permit rapid heart rates which could not otherwise be tolerated without elevations of atrial pressure. The fact that MLAP—LVEDP is independent of aortic pressure and stroke volume, and of heart rate over certain ranges suggests that this hemodynamic measurement is uniquely dependent on, and therefore useful in the analysis of, atrial performance.
