SUMMARY. We employed intracoronary infusion of adenosine deaminase to test the hypothesis that endogenous adenosine contributes to regulation of coronary blood flow following acute reductions in coronary artery pressure. In 16 closed-chest anesthetized dogs, we perfused the left circumflex coronary artery from a pressurized arterial reservoir and measured coronary blood flow following changes in perfusion pressure before and 10 minutes after the start of intracoronary adenosine deaminase, 5 U/min per kg body weight. Parallel studies showed that this dose of enzyme resulted in cardiac lymph adenosine deaminase concentrations of 3.2 ± 0.4 U/ml. Adenosine deaminase abolished the vasodilator response to intracoronary adenosine, 4 and 8 µg, but had no effect on the vasodilator response to intracoronary papaverine, 200 and 300 µg, demonstrating enzyme efficacy and specificity. Additional experiments demonstrated that adenosine deaminase reversibly attenuated myocardial reactive hyperemia following 5- and 10-second coronary occlusions by 30% (P < 0.05), evidence that the infused enzyme effectively degraded endogenous adenosine. However, adenosine deaminase did not alter the time course for coronary autoregulation or the steady state autoregulatory flow response over the pressure range between 125 and 75 mm Hg. Further, adenosine deaminase did not alter steady state coronary flow when perfusion pressure was reduced below the range for effective autoregulation (60–40 mm Hg). Such results show that adenosine is not essential for either coronary autoregulation or for the maintenance of coronary vasodilation when autoregulatory vasodilator reserve is expended.

(Circ Res 56: 517-524, 1985)

CORONARY autoregulation is the intrinsic ability of the heart to maintain its blood supply relatively constant in the face of fluctuations in perfusion pressure (Mosher et al., 1964; Cross, 1964). The mechanism underlying this fundamental adaptive flow response is unknown. According to the metabolic hypothesis, coronary autoregulation is initiated by flow-dependent changes in tissue levels of a metabolic substrate or a metabolite (Johnson, 1964; Rubio and Berne, 1975; Belloni, 1979; Feigl, 1983). Several studies have demonstrated increased adenosine production and release during conditions in which oxygen supply is reduced (Katori and Berne, 1966; Rubio and Berne, 1969; Rubio et al., 1974; Schrader et al., 1977). In one of these studies (Schrader et al., 1977), tissue adenosine content and adenosine release increased when perfusion pressure was lowered over the autoregulation range in isolated buffer-perfused guinea pig hearts. As the investigators point out, such a correlation only suggests, but does not prove, that adenosine is the primary determinant of changes in coronary resistance during autoregulation.

This study tests the hypothesis that endogenous adenosine is an essential mediator of coronary autoregulation. The hypothesis predicts that destroying interstitial adenosine should abolish autoregulation. Extending this inquiry to pressures below the autoregulation range tests a second hypothesis, namely, that endogenous adenosine mediates coronary flow only when autoregulatory vasodilator reserve is expended. In both sets of experiments, an intracoronary infusion of adenosine deaminase was used to destroy interstitial adenosine. Adenosine deaminase did not alter coronary pressure-flow relationships in either instance, new evidence that adenosine is not essential for coronary autoregulation.

Methods

Animal Preparation

Experiments were performed in 16 healthy closed-chest adult mongrel dogs (weight 25–35 kg). Animals were given morphine sulfate (3 mg/kg, sc) and anesthetized with α-chloralose (50 mg/kg, iv), with additional doses of chloralose given as needed throughout the experiment. The dogs were ventilated with oxygen-enriched room air by a positive pressure respirator to keep arterial oxygen tension between 100 and 125 mm Hg and carbon dioxide tension at 35 ± 5 mm Hg. Arterial pH was maintained at 7.40 ± 0.05 by an intravenous infusion of sodium bicarbonate (150 mm, 5 ml/kg per hr, iv) (Arfors et al., 1971).
The hematocrit averaged 38 ± 2%. Systemic pressure was measured in the aorta with a catheter passed retrograde from the femoral artery and a strain gauge pressure transducer. Rectal temperature was held at 37°C with heating pads. Heart rate was measured continuously with a cardiotachometer triggered from the electrocardiogram.

**Coronary Perfusion System**

Pressure in the circumflex artery was controlled by an extracorporeal perfusion circuit (Dole et al., 1981). The circumflex artery was perfused from a pressurized arterial reservoir through a metal cannula advanced through the right carotid artery into the ascending aorta and wedged in the proximal circumflex artery under pressure and flow monitoring as described by Smith et al. (1974). The reservoir was heated to maintain the temperature of the blood entering the cannula at 37°C. Coronary artery pressure was measured at the cannula tip through an external auxiliary tube opening at the distal end of the perfusion cannula. Blood passed from the reservoir through an electromagnetic flow probe before entering the coronary cannula. The pressure in the reservoir was controlled by means of two compressed air tanks connected in parallel, permitting arbitrary alterations in perfusion pressure. The seal between the cannula tip and circumflex artery was confirmed by observing the response of cannula tip pressure to inflow occlusion and by injecting saturated Evans blue solution into the coronary cannula at the end of the experiment as described previously (Dole et al., 1981). The dye injection also served to delineate the area of perfused myocardium which was removed and weighed in order to calculate coronary flow per unit of muscle mass. Blood coagulation in the extracorporeal perfusion circuit was prevented by infusion of sodium heparin (initial dose 500 U/kg, iv, then 250 U/kg, iv, every hour). The flow meter zero was determined by frequent coronary inflow occlusions. The flow probe was calibrated by timed blood volume collections after each experiment with blood from the experimental animal.

We have previously shown that this perfusion system does not alter systemic hemodynamics. Furthermore, coronary reactive hyperemia and autoregulation are not impaired with the cannula in place (Dole et al., 1981).

**Penetration of 131I-Adenosine Deaminase into Cardiac Intersitial**

Experiments in five dogs evaluated the concentration of 131I-adenosine deaminase in cardiac lymph during the intracoronary infusion of this enzyme. In these experiments, we used mongrel dogs anesthetized with sodium thiopental, 18 mg/kg, iv, and maintained in surgical anesthesia by ventilation with O2-enriched air containing 0.5% halothane. Surgical preparation entailed thoracotomy through the left 5th intercostal space to expose the heart. The order of occlusions was randomized and each observation began 10 minutes after the start of the adenosine deaminase infusion. Such a test documents the penetration of the enzyme into the cardiac interstitial space. To allow the enzyme time to penetrate into the cardiac interstitium, all experimental observations began 10 minutes after the start of the adenosine deaminase infusion.

We assessed the specificity of adenosine deaminase for adenosine in four animals by comparing the effects of intracoronary injections of adenosine and papaverine before and during adenosine deaminase infusion. Attenuation of coronary vasodilator responses to adenosine but not to papaverine would provide evidence for enzyme specificity.

Since attenuation of vasodilator responses to intracoronary adenosine by adenosine deaminase could be due to exogenous enzyme in the blood, in five animals we compared vasodilator responses in the coronary bed to those in the femoral bed before, during, and at 120 minutes after discontinuing the enzymatic activity of adenosine deaminase infusion. Selective inhibition of adenosine-induced vasodilation in the coronary bed would indicate that the effect of adenosine deaminase was due to enzyme retained in the heart and not to enzyme in the blood which should affect adenosine responses in both the femoral and coronary beds. In these experiments, the left femoral artery was cannulated and perfused through an extracorporeal circuit with blood into capillary tubes certified to contain 50 ± 1 µl. The 131I activity in this lymph and the 131I and enzymatic activity of the infusate served for calculation of lymph adenosine deaminase (ADA) concentration by the formula:

\[
\text{lumph ADA (U/ml)} = \frac{\text{infusate ADA (U/ml)} \times \text{lymph }^{131}\text{I (counts/min per ml)}}{\text{infuse }^{131}\text{I (counts/min per ml)}}
\]

Since the assay of adenosine deaminase activity is carried out at 25°C, but the cardiac interstitium is at 37°C, we compared initial rates of deamination of 0.1 mM adenosine at these two temperatures. At 37°C, the catalytic activity of adenosine deaminase was 1.95 times higher than the activity at 25°C.

**Functional Activity of Adenosine Deaminase**

Calf intestinal adenosine deaminase, type I, was obtained from Sigma as a suspension in 3.2 M (NH₄)₂SO₄, pH 6. The enzyme solution for intracoronary infusion consisted of 4000 U adenosine deaminase and 12 mmol Na₂HPO₄ in a total volume of 30 ml 0.14 M NaCl. The pH of the enzyme solution was 7.4. This solution was filtered through a 0.44-µm cellulose acetate membrane immediately prior to use. A solution containing the same proportions of (NH₄)₂SO₄ and Na₂HPO₄ in 0.14 M NaCl was infused into the coronary circulation during all control observations.

Two tests assessed the functional enzymatic activity of the adenosine deaminase. First, we determined the vasodilator response to a 4- and 8-µg intracoronary bolus of adenosine before, during, and at 120 minutes after the end of the adenosine deaminase infusion. Such a test ensures that the adenosine deaminase is catalytically active in our preparation. Second, we measured reactive hyperemic flow responses following 2-, 5-, and 10-second coronary inflow occlusions before, during, and at 60 minutes after discontinuing the adenosine deaminase infusion. The order of occlusions was randomized and each observation was the average of two occlusions for each duration. Occlusions were separated by at least 3 minutes. Such a test documents the penetration of the enzyme into the cardiac interstitial space. To allow the enzyme time to penetrate into the cardiac interstitium, all experimental observations began 10 minutes after the start of the adenosine deaminase infusion.

The concentration of adenosine deaminase was 1.95 times higher than the activity at 25°C.
from the dog's left common carotid artery. The circuit contained an in-line electromagnetic flow probe for measuring femoral blood flow.

**Experimental Protocol**

After the preparation had stabilized for 30-45 minutes, we recorded control heart rate, mean aortic pressure, coronary blood flow at a coronary perfusion pressure of 100 mm Hg, the coronary flow response to intracoronary adenosine, the coronary flow response to intracoronary papaverine, coronary reactive hyperemia after 2-, 5-, and 10-second inflow occlusions, and coronary artery pressure-flow curves. In nine animals, steady state coronary flow was determined at pressures of 125, 100, and 75 mm Hg. In seven of these animals, the dynamic flow response to a step changes in pressure between 125 and 75 mm Hg was also recorded. In seven separate animals, steady state coronary artery pressure-flow relationships were obtained over the range of 100–40 mm Hg by decreasing pressure in 20 mm Hg steps. Flow was allowed to stabilize at least 2 minutes between each pressure change.

Following control measurements, adenosine deaminase was infused into the circumflex coronary bed at a rate sufficient to deliver 5 U/min per kg. At the 10th minute of enzyme infusion, we repeated all of the experimental observations. The adenosine deaminase infusion then was stopped and a final set of measurements of all experimental parameters was obtained 1 hour later. The responses to intracoronary injections of adenosine were also recorded at 120 minutes after infusion was discontinued.

At the completion of the experiment, Evans blue was injected into the perfusion cannula at the maximum coronary artery pressure used during the experiment, and the animal was killed by intravenous injection of saturated potassium chloride. The heart then was removed and the stained area weighed.

**Quantification of Autoregulation**

The degree of autoregulation was quantified by calculating the closed loop gain of the system (Norris et al., 1979) as

$$G_A = 1 - \frac{(\Delta F/F)/(\Delta P/P)}$$

where $F$ is the steady state flow at pressure $P$, and $\Delta F$ is the change in flow for a given change in pressure $\Delta P$. Values for $G_A$ greater than zero indicate the degree of autoregulation with a maximum value of 1. Values of $G_A \leq 0$ indicate a lack of autoregulation, i.e., a passive vascular bed.

We characterized the time course of the autoregulatory response by measuring $t_m$, the time for mean coronary flow to return 50% of the way to control after a step change in pressure, and also by measuring the time for flow to reach a steady state.

**Data Analysis**

Hemodynamic data before and after adenosine deaminase were compared by Student's $t$-test for paired observations. Differences in pressure-flow data, responses to drugs, and reactive hyperemic flow responses before, during, and after adenosine deaminase were assessed by analysis of variance and Tukey's test for multiple comparisons (Snedecor and Cochran, 1980).

Reactive hyperemic flow—defined as the volume of flow greater than control flow rate—and peak reactive hyperemic flow were determined, and the data from two occlusions for each duration were averaged and expressed as a percent change from the control response. Differences between means were considered to be statistically significant when $P$ was less than 0.05. All data are expressed as mean ± SEM.

**Results**

Control hemodynamic parameters for all 16 animals at a circumflex perfusion pressure of 100 mm Hg were: heart rate 132 ± 7 beats/min, mean aortic pressure 115 ± 6 mm Hg, and mean coronary flow 78 ± 3 ml/min per 100 g. The corresponding values during infusion of adenosine deaminase were 128 ± 8 beats/min, 116 ± 6 mm Hg, and 77 ± 3 ml/min per 100 g; at 60 minutes after discontinuing adenosine deaminase, they were 130 ± 8 beats/min, 113 ± 8 mm Hg, and 80 ± 4 ml/min per 100 g. These changes are not significant.

**Effects of Adenosine Deaminase on Coronary Autoregulation**

Figure 1 shows the effects of adenosine deaminase on steady state coronary flow over the pressure range of 125 to 75 mm Hg in nine animals. Control flow averaged 80 ml/min per 100 g at a pressure of 100 mm Hg and was not altered by adenosine deaminase. The autoregulatory gain for a step reduction in pressure from 125 to 100 mm Hg averaged 0.53 ± 0.04 during the control period prior to adenosine deaminase and 0.50 ± 0.05 during adenosine deaminase infusion. These values were not significantly different. The control gain for a reduction in pressure from 100 to 75 mm Hg averaged 0.56 ± 0.06 and was not altered during adenosine deaminase infusion ($G_A = 0.58 ± 0.06$).

Figure 2 shows the effects of adenosine deaminase on the coronary flow response to a step change in pressure between 125 and 75 mm Hg. Following a reduction in pressure, coronary flow initially decreased and then returned toward control, reaching
a new steady state within 36 seconds. Following an increase in pressure, coronary flow rose transiently and then declined, reaching a new steady state within 25 seconds. Table 1 summarizes the effects of adenosine deaminase on the time course of coronary autoregulation in seven animals. Adenosine deaminase did not affect the dynamic flow response to a pressure change in either direction.

Effects of Adenosine Deaminase on Coronary Pressure Flow Relations below the Autoregulatory Range

Figure 3 shows the effects of adenosine deaminase on steady state coronary flow responses to 20 mm Hg reductions in pressure over the range between 100 and 40 mm Hg in seven animals. Whereas there was no difference in control flow when pressure was reduced from 100 to 80 mm Hg, pressure reductions below 80 mm Hg resulted in a progressive decrease in flow. Adenosine deaminase did not alter the flow response to pressure change even at pressures below the autoregulation range.

Figure 4 plots the degree of autoregulation expressed as the gain, GA, for each pressure step before and during adenosine deaminase infusion. There was a decrease in the degree of autoregulation when initial pressure was lowered from 100 to 80 mm Hg. Between 60 and 40 mm Hg, autoregulation was totally abolished, as indicated by the negative gain. Despite the progressive reduction in the degree of autoregulation, adenosine deaminase had no effect on the flow response to pressure change.

Cardiac Lymph ¹³¹I-Adenosine Deaminase

Lymph flow rate varied between about 6 and 20 µl/min as judged by the time necessary to fill a 50-µl capillary pipette. Accordingly, the number of lymph samples collected during the 20 minutes of ¹³¹I-adenosine deaminase infusion was three in 2 dogs, five in 2 dogs, and eight in 1 dog. As shown in Figure 5, lymph ¹³¹I-adenosine deaminase activity rose throughout the period of infusion, reaching an average value of 3.2 ± 0.4 U/ml (range 2.2-4.5 U/ml). The time course of lymph ¹³¹I-adenosine deaminase activity showed an initial rapid rise followed by an asymptotic approach to the maximum

value. Thus, by the 10th minute of enzyme infusion, lymph $^{131}$I-adenosine deaminase concentration averaged 84% of maximum (range 74–95%). Lymph $^{131}$I activity declined rapidly after the end of the enzyme infusion, but levels were still appreciable, approximately 0.5 U/ml, 20 minutes later (data not shown).

Functional Activity of Adenosine Deaminase

Figure 6 (panels A and B) summarizes the effects of adenosine and papaverine in the coronary bed before, during, and after intracoronary administration of adenosine deaminase. During control conditions, adenosine (4 and 8 µg) increased coronary flow by 124 ± 9% and 200 ± 24%, respectively. Adenosine deaminase totally abolished the vasodilator response to intracoronary adenosine during the enzyme infusion and for as long as 120 minutes after discontinuing the enzyme infusion. Papaverine in doses of 200 and 300 µg increased control coronary flow by 90 ± 15% and 120 ± 22%, respectively. The coronary vasodilator response to papaverine was unchanged during infusion of adenosine deaminase, demonstrating enzyme specificity. The intra-arterial injection of 10- and 20-µg doses of adenosine into the femoral bed increased mean femoral flow by 79 ± 14% and 118 ± 14%, respectively. In contrast to responses in the coronary bed, the vasodilator response to adenosine in the femoral bed (Fig. 6, panel C) was attenuated only during the enzyme infusion, and returned to control levels 120 minutes after the enzyme infusion was stopped. Thus, the prolonged inhibition of adenosine-induced coronary vasodilation was not due to adenosine deaminase still circulating in the blood, but rather reflected the action of residual enzyme in the heart.

The effects of adenosine deaminase on coronary reactive hyperemia are summarized in Table 2. During control conditions, the ratio of peak reactive hyperemic flow to basal flow averaged 1.5 ± 0.1 for 2-second occlusions, 2.4 ± 0.1 for 5-second occlusions, and 3.3 ± 0.3 for 10-second occlusions. Peak reactive hyperemic flow was modestly reduced (10%, P < 0.05) only with 5-second occlusions. Adenosine deaminase reduced reactive hyperemic flow by approximately 30% (P < 0.05) following 5- and 10-second coronary occlusions and by 8% (P < 0.05) following 2-second occlusions.

Discussion

The major finding in this study is that intracoronary infusion of adenosine deaminase at a concentration sufficient to attenuate myocardial reactive hyperemia did not affect the coronary artery pressure-flow relationship when pressure was reduced over the autoregulation range or to levels even below this range.

Additional experiments demonstrated that adenosine deaminase was efficacious, selective, and had penetrated into the cardiac interstitial space. An intracoronary infusion of the enzyme abolished the coronary vasodilator response to adenosine but did not alter the response to papaverine, evidence of enzyme efficacy and specificity. Further, a comparison of the vasodilator responses to exogenous adenosine in the coronary and femoral beds 2 hours after the intracoronary adenosine deaminase infusion had been discontinued showed that the coronary response was still markedly attenuated, whereas the femoral response was fully restored. This finding indicated that suppression of the coronary response resulted from enzyme retained in the heart rather than from enzyme in the blood. The observation that adenosine deaminase attenuated myocardial reactive hyperemia following 5- and 10-second occlusions by 30%, provides functional evidence that infused enzyme penetrated into the cardiac interstitium. Finally, the studies of 131I-adenosine deaminase confirm quantitatively that during intracoronary adenosine deaminase infusion, substantial amounts of the enzyme penetrate into the cardiac interstitium.

The collection of lymph from an epicardial lymphatic channel probably is the most direct way to probe the composition of the interstitial space of the perfusion field receiving 131I-adenosine deaminase. Unlike lymph sampled at more remote sites, the lymph is unlikely to be diluted by lymph draining from regions not receiving enzyme directly, and thus more nearly represents the true value. Nevertheless, we believe that our measurements of lymph adenosine deaminase concentration are a minimum estimate of the catalytic activity of the enzyme in the interstitial space. Owing to the transit time of 131I-adenosine deaminase from the interstitium to the lymph collecting site and the averaging effect of sample collections lasting several minutes, the concentration in lymph at any moment will be less than that in the interstitium. Additionally, lymph adenosine deaminase activity does not reflect the extent to which enzyme binds to adenosine deaminase binding proteins (Daddona and Kelley, 1977; Schrader and Stacy, 1977) on the surface (Kornfield, 1983) of the cells which constitute the boundary of the interstitial space. Adenosine deaminase thus bound retains catalytic activity and augments that of enzyme in solution. Finally adenosine deaminase activity is, by convention, measured at 25°C. The catalytic activity in interstitium at 37°C was 1.95 times higher.

The use of adenosine deaminase to probe the participation of adenosine in coronary autoregulation raises a critical question: Does enough enzyme penetrate into the interstitial space to destroy adenosine as fast as it is formed? We do not know of a method for directly measuring the rate of release of adenosine into the cardiac interstitium. However, it is possible to calculate how much adenosine production would have to increase in order to maintain adenosine concentrations constant in the presence of adenosine deaminase. Such calculations make allowances for the temperature differential between the cardiac interstitium and the in vitro assay, assume that the interstitial space volume is 0.217 ml/g (Frank and Langer, 1974), and accept the basal interstitial adenosine concentration of 0.2 μM (Ols-

Circulation Research/Vol. 56, No. 4, April 1985
In these experiments, circumflex artery pressure was regulated independently of aortic pressure; thus, pressure gradients could have resulted in intracoronary collateral flow. Although early work by Driscoll et al. (1964) demonstrated that the pattern of coronary flow in response to changes in perfusion pressure was not altered by sizeable pressure gradients between major vessels, more recent data suggest that collateral flow may influence the steady state pressure-flow relationship in the circumflex artery at low perfusion pressures (Messina et al., 1983). Although coronary flow may have been underestimated at the lower perfusion pressures in the present study, the gradient for collateral flow was the same before and during adenosine deaminase infusion. Thus, the failure of adenosine deaminase to alter coronary flow responses to pressure change cannot be attributed to differences in collateral flow.

Our experiments in blood perfused in situ dog hearts lead to a conclusion diametrically opposite to that reached by Schrader et al. (1977) who studied isolated, buffer-perfused guinea pig hearts. Differences in the characteristics of autoregulation, perhaps related to the preparations or to the species, and also a fundamental difference between the experimental designs, may explain the discordant conclusions. Coronary autoregulation in the guinea pig preparation occurred between pressures of 60 and 20 cm H2O (44-15 mm Hg), which is below the pressure range for autoregulation which we and others have observed in the blood-perfused dog heart (Mosher et al., 1964; Cross, 1964; Guyton et al., 1977; Rouleau et al., 1979; Dole et al., 1981, 1982). An inverse correlation between adenosine release rate and coronary perfusion pressure in the guinea pig was the major element of support for the hypothesis that adenosine mediates coronary autoregulation. In our study, destruction of cardiac interstitial adenosine provides a direct test of the role of this nucleoside in coronary autoregulation.

Our conclusion that adenosine is not essential for coronary vasodilation following reductions in perfusion pressure is consistent with recent work by Gewirtz et al. (1983) in a closed chest conscious pig model. In that study an intracoronary infusion of adenosine deaminase had no effect on regional myocardial perfusion beyond a flow-limiting coronary stenosis which reduced post-stenotic pressure to 77 mm Hg at a mean aortic pressure of 117 mm Hg. These authors point out that measurements of steady state coronary pressure and flow do not exclude the possibility that the effect of adenosine is transitory and might be essential in initiating but not maintaining coronary vasodilation. The present study shows that such is not the case, since adenosine deaminase did not alter the time course of coronary autoregulation.

A recent preliminary report by Hanley et al. (1984) also showed that adenosine deaminase does not alter coronary autoregulation. In addition, these investigators estimated interstitial adenosine concentrations by means of an epicardial well technique (Hanley et al., 1983) and found that adenosine concentration was the same at high and low perfusion pressures within the plateau of the coronary pressure-flow curve.

The attenuation of canine myocardial reactive hyperemia by intracoronary adenosine deaminase in the present study confirms a previous report by Saito et al. (1981) and indicates that adenosine can account for at least 30% of the hyperemic flow following coronary occlusions ≥5 sec. The additional finding that adenosine deaminase had little effect on reactive hyperemia following 2-second occlusions suggests that adenosine does not play a major role in flow regulation following relatively short coronary occlusions.

There is a potential limitation to the interpretation of experiments designed to assess the contribution of a single mediator to a physiological response which is the resultant of several, interacting mediators. In such a case, blocking or destroying one mediator could elicit a compensatory increase in the contribution of another such that the response is unaltered. Accordingly, we recognize the possibility that coronary autoregulation or myocardial reactive hyperemia may result from the concerted action of adenosine and other, as yet unidentified, vasodilator mechanisms which are capable of compensating when adenosine is destroyed.
