Characteristics of Junctional Regions Between Purkinje and Ventricular Muscle Cells of Canine Ventricular Subendocardium

David A. Rawling and Ronald W. Joyner

The normal cardiac activation sequence requires propagation of the action potential from the subendocardial Purkinje (P) network into the underlying ventricular muscle cells. This process occurs at specific junctional sites distributed over the endocardial surface of both ventricles. At these junctional sites, action potentials can be recorded from cells that appear to be interposed between the Purkinje cells and the ventricular muscle cells. The action potential upstrokes recorded from these "transitional" cells have characteristic double phases produced by electrotonic interactions with the Purkinje cells and the ventricular muscle cells. We have shown that these junctional regions in the canine subendocardium appear to be fixed anatomic sites with locations independent of the activation sequence of the Purkinje network. In addition, the activation delay between the Purkinje cells and the ventricular muscle cells at a junctional site and the patterns of the action potential upstrokes of transitional cells at a junctional site are independent of the activation sequence of the Purkinje network. We have also demonstrated that at some locations there are multiple Purkinje activation signals recorded with a surface electrode and that these multiple activation signals represent discrete groups of Purkinje cells, some of which contribute to the junctional process while others appear to be substantially uncoupled from neighboring Purkinje cell groups and the underlying transitional cells.

(Circulation Research 1987;60:580-585)
the regularly occurring excitation, suggesting a prolonged refractoriness of the T cell. Current injection into T cells at a junctional site was shown to decrease or increase junctional delay with depolarizing and hyperpolarizing current injections, respectively.

One possibility not excluded by previous work is that the cells recorded as T cells are not actually specialized in terms of their intrinsic membrane properties but that the appearance of their rising phase is simply due to electrotonic interactions that modulate the cell into a T cell action potential configuration. If this hypothesis is true, the actual location of PVJ sites and the action potential upstroke of cells recorded as T cells could vary with changes in the activation sequence of the P layer. The alternative hypothesis is that PVJ sites are fixed anatomic entities with a specialized structure of T cells such that when local P activation occurs, the T cells at the PVJ site follow a standard activation sequence, thereby producing a PVJ delay and a set of T cell action potential configurations that is independent of the activation sequence within the P layer. The results presented in this paper support the latter hypothesis.

Materials and Methods

The recording and stimulating methods used have been previously described in detail. A left ventricular (LV) papillary muscle or a portion of the LV septum or free wall was obtained from the heart of a mongrel dog after the heart had been removed under sodium pentobarbital anesthesia. The preparation was allowed to recover for 1 hour in the experimental chamber before data collection began. The chamber was perfused with Tyrode's solution of the following composition (in mM): NaCl 125, NaH2PO4 0.4, NaHCO3 24, KCl 4, MgCl2 1,CaCl2 2.7, and dextrose 5.5, pH 7.35. The solution was continuously gassed with a 95% O2-5% CO2 mixture, and chamber temperature was maintained at 36-37° C. All preparations were stimulated at a frequency of 1 Hz using square wave pulses 0.5-1 msec duration with amplitudes 1.5-2 times diastolic threshold. In preparations on which two pacing sites were used, the second stimulating electrode was placed so that at the PVJ site, the direction of propagation of the P layer action potential wavefront stimulated by the second electrode was at approximately right angles to that stimulated by the first electrode.

Extracellular recordings were made on the endocardial surface of the preparation, using a monopolar electrode with a reference electrode located approximately 1 mm above the preparation surface. Intracellular recordings were obtained with conventional glass microelectrode techniques. Data from both types of recordings were amplified and digitally sampled by an analog to digital converter system (12-bit resolution, sampling rate 5,000-10,000 samples/channel/sec) interfaced to a VAX 11/780 computer system. Data analysis was done by interactive cursor controlled measurements of activation times using a Tektronix 4014 graphics terminal.

Table 1 gives the results for all 11 experiments. For each experiment, whether 0.5-mm or 1-mm map spacing was used, minima in P-V delay were determined for each stimulation direction from the P-V difference maps. P-V difference minima were then defined as representing separate PVJ regions if the individual minima centers were separated by at least 4 mm. Finally, the actual P-V difference times for each recording point within the PVJ region were used to calculate the average PVJ delay for each PVJ region. In every experiment, the location of the PVJ region(s) did not change when the P layer was stimulated at the two selected sites. In addition, as shown in Table 1, the PVJ delays at these regions were virtually the same regardless of the direction of P layer action potential propagation into the PVJ regions.

In 8 of these experiments, microelectrode recordings were made from individual cells to see what happened to the cells' action potentials and activation time with altered PVJ activation direction. Some of the cells fit the description of the T cells of Alanis and Benitez and Matsuda et al. Figure 2 shows the initial portions of action potentials of P, T, and VM cells sequentially penetrated at a PVJ site (as determined from extracellular mapping). For these experiments, an action potential was defined as a T cell action potential if it had the following characteristics: 1) Its phase 0 depolarization was not smooth but had variable depolarization (1.e., phase 0 had bumps or notches), and/or there was a "hump" on the early portion of the plateau. 2) The time of occurrence of its [dV/dt]max fell between the times of P layer and VM layer activation at the PVJ (as determined from an extracellular recording made at the PVJ). 3) Its overall appearance and duration were similar to those of a VM cell action potential. As in Figure 1, the X and Y stimulation sites were located so that the P layer action potential wavefronts induced by these two bipoles entered the PVJ in directions approximate-
FIGURE 1. Isochronal activation maps for a canine left septal endocardial preparation. Surface recordings were sequentially made at 0.5-mm spacings (as indicated by dots) during repetitive 1 Hz pacing of Purkinje system from 2 stimulus sites (X and Y). As each surface point was recorded, data were taken with stimulus alternatively applied to location X and location Y. Parts A, B, and C: P activation times, VM activation times, and P-V difference times, respectively, when stimulus was applied to location X. Parts D, E, and F: P activation times, VM activation times, and P-V differences for same surface locations but recorded during stimulation at location Y. See text for discussion.

Linear regression: slope, 0.96; intercept, 0.27; r = 0.97; n = 17.

Several important findings regarding T cells are illustrated by Figure 2. First, T cells do not appear to occur as single, isolated cells or a single, electrically well-coupled group of cells linking the P and VM cells at the PVJ. Second, Figure 2 demonstrates that T cells appear to be activated in a linear sequence since the order of action potential recordings shown is the same as the sequence in which the cells were recorded from as the recording microelectrode was advanced at the PVJ site. This same spatial/temporal relation was found in a total of 17 sets of recordings in which two or more T cells were sequentially penetrated; in all cases each successively deeper T cell action potential always fired after its more superficial predecessor.

A third finding illustrated by Figure 2 is that the T cells remained T cells even though the direction of P layer activation into the PVJ changed. This consistency of T cells as T cells was observed in recordings from 54 T cells. Fourth, comparison of the shapes of the T cells' phase 0 with the two activation directions shows them to be very similar, suggesting that the electrical inputs to and loading of the T cells were the same for...

PAPILLARY MUSCLE

This finding suggests that the sequence of T cell activation traveling transverse to long axis of muscle (X stimulation) or P activation traveling along long axis of muscle (Y stimulation). Results from each stimulation site are shown in upper and lower panels, respectively. As each intracellular penetration was made, intracellular action potential and surface potential (shown below action potentials) were recorded for each stimulus site. Since the arrival time of the P activation at the PVJ site was different for both stimulus sites, "Y STIM" recordings were shifted by a constant time to align in time peak negativity of VM component of surface recordings for both stimulus sites.

Finally, Figure 2 shows that the relative times of T cell activation with the two stimuli do not change. These findings suggest that the sequence of T cell activation is anatomically defined and thus does not vary with the direction of action potential propagation into the PVJ. Further support for this hypothesis is illustrated in Figure 3. The relative times (with respect to the PVJ delay) of T cell activation for two directions of P activation for 25 T cells from 4 different experiments are plotted in this figure. The graph shows clearly that the relative time of T cell activation remained almost the same, with respect to the temporal sequence of PVJ activation, regardless of the direction of PVJ activation.

In 3 preparations (2 endocardial and 1 papillary muscle), analysis was somewhat complicated by the presence of more than one P signal in the extracellular recording. In addition, the temporal relation between these P signals varied with the direction of P layer activation, as illustrated in Figure 4. Figures 4A and C show the VM activation maps produced by X and Y stimulation, respectively; these maps confirm the identical location of the PVJ with the two stimuli. B and D show extracellular recordings from around the actual PVJ site (locations marked A, B, D, E), and from the PVJ site itself (location c, which was determined to be the PVJ site based on our previously published PVJ criteria). At c, 3 P signals were present, and these signals changed their temporal relation with the two different stimulation sites.

Figure 5 shows the initial portions of 4 action potentials recorded from cells near c. The extracellular recording electrode was moved a short distance (about 200 μm) from c to place it closer to the microelectrode. In addition, the starting time for plotting all recordings with Y site stimulation was shifted a fixed amount to time-align the peak negative deflections of the extracellular VM signals generated by the two stimuli. Note that while the activation time of P cell action potential "P," shifted with the change in PVJ activation direction (expressed with respect to the time of VM activation in the extracellular recording), the activation times of both P cell action potential "P," and T cell action potential "T" remained fixed with respect to each other and to the time of VM activation (and the time of the VM cell activation). These results suggest that at some PVJs, there are portions of the P network that are not directly electrically connected to the T cells of the PVJ at that site but are merely "passers-by.”

In the two other preparations (not shown) in which similar recordings were made, it was again found that only one of the P signals shifted in conjunction with the changes in T cell and VM cell activation time, further supporting the notion that specific P “strands” are connected to the VM through the T cells of the PVJ and that the activation sequence of cells through the PVJ are fixed.

Discussion

The results presented here demonstrate that PVJ sites are anatomically fixed and that the sequence of activation times (P cells to T cells to VM cells) is
indipendent of the direction of P layer propagation. On the other hand, some endocardial regions were shown to have a superficial Purkinje layer that cannot be represented as an electrically interconnected two-dimensional sheet since at numerous locations there appeared to be multiple P activation times recorded by surface electrodes. Also, the microelectrode recordings showed that these multiple P activation signals corresponded to groups of P cells with no apparent local electrical coupling to each other. This observation raised the interesting hypothesis that at some PVJ sites there could be multiple inputs into the T cells from these discrete groups of P cells. However, in the experiment shown in Figures 4 and 5 (and in 2 additional experiments), there was no evidence to support this hypothesis. In all of these preparations, one group of P cells had an activation time that was fixed in association with the succeeding T cell activation times and the VM cell activation time, while the other group of P cells had an activation time that had a variable relation with the T and VM cell activation times depending on the stimulus location.

However, the demonstration that the complicated upstroke patterns of T cell action potentials did not vary with the direction of action potential propagation in the P layer does not imply that these upstroke patterns are therefore due to the intrinsic properties of the T cell membrane conductances. It has been convincingly shown that these multicomponent upstroke patterns are produced by electrotonic interactions mediated by the anatomic relations between T cells and VM cells. The present study demonstrates that once the process is initiated by the arrival of the action potential in the P cells that couple to the most superficial T cells, the subsequent steps in the junctional process appear to follow a fixed time sequence. This time sequence, however, can be altered at a given PVJ site by altered excitability or by alterations in cell-to-cell electrical coupling.

It is interesting to compare the P to VM junctional sites with the AV node, which can be considered a junctional region between atrial cells and the bundle of His. In the AV node, Janse demonstrated that the sequence of AV nodal activation was altered when the location of atrial stimulation was changed. In fact, not only was the AV nodal conduction time altered, but the
action potentials recorded from individual cells in the AV node had different patterns of their rising phases with different atrial stimulus locations. More recently, Mazgalev et al. and Iinuma et al. have shown that dual inputs into the AV node from the atrium produce complex patterns of apparent summation that can lead to changes in AV node conduction time, AV node refractory period, and the sensitivity of AV node refractory period to verapamil.

In contrast to the AV nodal junctional process, the P to VM junctional process seems to be designed in a fundamentally different way. In the ventricles, there appears to be a large number of spatially discrete junctional complexes, each with a delay of only a few milliseconds. Also, in the P to VM junctions, there is apparently a simpler geometric relation between the P cells, T cells, and VM cells than that found between atrial cells, AV nodal cells, and His bundle cells. This arrangement of multiple, independently acting PVJ sites thus forms a parallel system so that multiple sites of activation of the ventricular subendocardial muscle can occur to increase the degree of synchrony of ventricular activation and thus the degree of synchrony of ventricular contraction.
