Effect of Amiodarone on the Expression of Myosin Isoforms and Cellular Growth of Cardiac Muscle Cells in Culture

Asish C. Nag, Mei Li Lee, and Deborah Shepard

The effect of amiodarone on the expression of myosin isoforms and the growth of neonatal rat cardiac muscle cells in culture was studied by native gel electrophoresis, assays of DNA and protein synthesis, and electron microscopy. Cardiac myocytes exposed to amiodarone in the absence of triiodothyronine (T₃) showed predominant V₃. When cardiac myocytes were exposed to amiodarone in the presence of T₃, they expressed prevalent isomyosin V₃, or both V₃ and V₁ equally. Supraphysiological concentration of T₃ counteracted the effect of amiodarone on myocytes, showing the expression of predominant isomyosin V₁. Amiodarone has inhibitory effects on DNA synthesis and differentiation of cardiac myocytes. Myocytes treated with amiodarone showed maximum labeling index with 11% labeled cells after day 1. Subsequently, the labeling indexes declined and on the third day ceased, as opposed to the control culture, which attained a peak in labeling index with 60% labeled myocytes on the third day. The labeling indexes declined, showing 11% labeled myocytes at the terminal time point. Myocytes treated with amiodarone lost most of the well-organized myofibrils and other organelles, and instead contained sparse, scattered segments of myofibrils, free myofilaments, many mitochondria with disrupted cristae, and autophagic vacuoles. The results demonstrated that amiodarone has a direct influence on the expression of isomyosin by cardiac myocytes. Furthermore, this drug has inhibitory and degrading effects on the growth and differentiation of cardiac myocytes. (Circulation Research 1990;67:51–60)

Amiodarone, a benzofuran derivative and a potent antiarrhythmic drug, has been used extensively for the treatment of cardiac arrhythmias and angina¹,² in many countries and recently was introduced for use in the United States. Studies of amiodarone's effect on the heart have offered two types of findings by different groups of investigators. One has suggested that the chronic treatment with amiodarone may have effects that resemble those of hypothyroidism.¹⁻⁹ Another finding has indicated that both hypo- and hyperthyroidism occurred in some patients treated with amiodarone for cardiac arrhythmias or angina.¹⁰,¹¹ Ikeda et al¹² reported that amiodarone caused prolongation of repolarization in cardiac tissue. This type of repolarization was found to be an effect produced by thyroidectomy in rabbits.⁴ It was observed that simultaneous administration of thyroxine (T₄) inhibited amiodarone-induced lengthening of repolarization of atrial and ventricular action potentials.⁵ In addition, amiodarone has been found to cause a number of characteristic features of hypothyroidism such as bradycardia,⁶,⁷ prolonged systolic time intervals,⁸ and a decrease in Ca²⁺-ATPase activity of cardiac myosin.⁹ Lindenmeyer et al⁹ have been able to revive the bradycardia by administration of supraphysiological doses of triiodothyronine (T₃). Bagchi et al⁹ reported that amiodarone treatment for 6 weeks in rats resulted in lower heart weight, decreased atrial production of¹⁴C-CO₂ from labeled glucose, decreased myosin Ca²⁺-ATPase activity, and more synthesis of V₃ isomyosin compared with that of the control. These effects were similar to those observed in hypothyroid rats but were lesser in magnitude. Although the effects of amiodarone treatment suggest hypothyroidism, serum T₄ is increased during amiodarone treatment, and serum T₃ remains in the normal range.⁹,¹⁰ Martino et al¹² reported the occurrence of hypo- and hyperthyroidism after chronic treatment with amiodarone. Hyperthyroidism showed elevation in serum T₃ or free T₃ concentrations, and hypothyroidism was best diagnosed by showing an elevated serum thyrotropin concentration. Both hypo- and hyperthyroidism have been noted to occur in some patients treated with amiodarone when the patients with hypothyroidism

had subnormal T4 levels, and the patients with hyperthyroidism had elevated T4 levels.13
Past studies have been carried out in the in vivo system where various endogenous factors might control the drug actions in the body. The present study examines the effect of amiodarone on cardiac muscle cells that have been cultured and exposed to amiodarone in the presence or absence of exogenous thyroid hormone. The specific objective of this study is to investigate the influence of amiodarone on the expression of myosin isoforms and cellular growth of cardiac muscle cells in culture in the presence or absence of thyroid hormone. The rationale for the presence or absence of thyroid hormone in the culture is to examine whether there is interaction between the drug and thyroid hormone in the expression of isomyosins and the growth of cardiac myocytes.

Materials and Methods

Cell Culture

Ventricles of 4- to 5-day neonatal rats were used for isolation of cells. The isolation procedure was the same as those of our previous studies.14,15 Briefly, the ventricular tissue mince was dissociated into single-cell suspension by incubation in 0.15% trypsin, 0.025% collagenase, 4% chicken serum, and 96% Ca2+- and Mg2+-free Tyrode’s solution. The ventricular cells were incubated in a basic medium containing 99% Eagle’s basal medium with Earle’s salts, 1% bovine serum albumin, norepinephrine (10-5 M/ml), insulin/transferrin/selenium mixture (0.1/100 ml), ascorbic acid (0.02 mg/ml), epidermal growth factor (10 ng/ml), 2% calf serum, and 1% penicillin/streptomycin mixture. To grow cells in the presence of amiodarone, at least 2% serum is needed. The cells were grown in three experimental conditions: one set of culture was grown in the above medium with amiodarone (30–40 μg/ml) (amiodarone was a gift of Dr. A. Urdang, Sanofi, New York); the second set of culture was grown in the above medium with T3 (10-5 M/ml) and amiodarone with the same concentrations as above. The growth medium of the third set was the same as in the second one with the exception of the T3 dose, which was three times the second set. The maximum dose of this drug was determined on the basis of experimentation that showed cell death at a higher concentration than the doses used. Controls for three sets of cell culture were grown in their respective culture media without amiodarone. The cells were plated at a density of 1×106 cells per 35-mm dish and cultured for 7 days in an incubator in a humidified atmosphere of 5% CO2 in air. The cultures were terminated at intervals of 4 and 7 days of culture for biochemical studies. Eleven experiments were carried out for these studies.

Preparation of Myosin and Cells

The cultured cells were scraped out of the plates with a plastic scraper at selected intervals as mentioned above. Myosin extraction was carried out follow-

ing our previous method14 with certain modifications. Briefly, the cells were homogenized by a Dounce homogenizer (Corning Glass Works, Parkridge, Ill.) in a buffer containing (mM) NaCl 40, EGTA 5, Na2HPO4 3, and phenylmethylsulfonyl fluoride 1 (pH 7.2). The homogenate was centrifuged at 7,974g for 20 minutes, and the pellet was immersed and centrifuged at 139,238g for 3 hours in a modified extraction solution16 containing 100 mM Na2HPO4, 15 mM 2-mercaptoethanol, 1 mM phenylmethylsulfonyl fluoride, and 2 μg/ml leupeptin (pH 8.8). The supernatant was collected and used for electrophoresis. Myosin from intact neonatal and adult ventricles was prepared by extracting tissue homogenate with 20 vol of the above extraction buffer. Protein concentration was determined by the method of Bio-Rad (Richmond, Calif.).

Electrophoresis

Pyrophosphate gels were prepared following essentially our previous method14 with minor modifications that included 3.88% acrylamide and 0.12% bisacrylamide in a buffer containing 20 mM Na2HPO4 (pH 8.8), 2 mM cysteine, and 10% glycerol (vol/vol). A prerun of 1 hour was carried out under conditions identical with those of electrophoresis with a constant 78 V. Myosin samples (100 μl) in 50% glycerol were loaded directly on the top of the gels, and electrophoresis was run overnight (16 hours) with a constant 90 V. Staining and densitometer tracing of gels were essentially the same as those in our previous studies.14,17

Assay of [3H]Thymidine Incorporation

Into Heart Cells

Cells were continuously exposed to 1 μCi/ml [3H]thymidine (TdR) for 24 hours before termination of cultures. The cultures were terminated at intervals of 1, 2, 3, and 5 days of incubation, and cells were scraped out of the plates after rinsing in cold 0.01 M phosphate buffer (pH 7.5) containing 0.01 M sodium pyrophosphate. Subsequently, the cells were pelleted by centrifugation, suspended in sodium pyrophosphate, and solubilized in 0.05N NaOH. The solution was then assayed for radioactivity in toluene-based scintillation fluid in a Packard Tri-Carb scintillation counter (Packard Instrument Co., Downers Grove, Ill.) as described previously.18

Assay of Cellular Protein

The cells were collected from the culture dish by gently scraping them out with a rubber policeman. The cells were then pelleted by centrifugation and subsequently suspended in phosphate-buffered saline followed by solubilization in 0.05N NaOH. Aliquots were taken for protein estimation using the Bio-Rad Coomassie blue assay. Data, expressed as micrograms of protein, are the means of determinations made on six or more individual tissue culture dishes.
Autoradiography and Periodic Acid-Schiff Technique

Cells were labeled with the same dose and length of exposure to [3H]TdR as described above. The cells were fixed in cold formaldehyde:alcohol (1:9) for 24 hours at 4°C and subsequently processed for periodic acid-Schiff (PAS) technique and autoradiography as described previously.18,19 Cardiac muscle cells were identified by PAS technique that stains cardiac muscle cells for their glycogen content.18,20 For scoring labeling indexes, at least 200 cells were counted under a light microscope. Triplicate plates were used for each time point, and pooled results of five experiments were recorded as mean values for labeled or unlabeled cells with their standard deviation.

Electron Microscopy

The cells in monolayer were processed for electron microscopy after 1, 3, 5, and 7 days of culture, following our previous methods.20,21 Essentially, the methodology involves rinsing cultured cells in Tyrode's solution several times and fixating them in half-strength Karnovsky's fixative20 for 1.5 hours at room temperature. The cells then were rinsed in cacodylate buffer (pH 7.4) several times and post-fixed in 1% osmium tetroxide for 1.5 hours at 4°C. The fixed cells were embedded in situ in Epon 81222 after dehydration. The embedding consisted of two stages. First, polymerization of Epon was carried out at 55°C overnight, and subsequently the embedded culture was peeled off the flask. Second, the peeled embedded culture was polymerized further at 60°C for 24 hours for proper hardening. Thin sections were prepared and stained with uranyl acetate and lead citrate. Sections were examined and photographed in a Philips Electronic Instruments 410 LS electron microscope (Mahwah, N.J.) operated at an accelerating voltage of 60 kV.

Results

Myosin from neonatal rat cardiac myocytes in culture was examined by pyrophosphate gel electrophoresis. The culture was exposed to amiodarone under three experimental conditions as follows: 1) myocyte culture was exposed to amiodarone (30–40 μg/ml) in the absence of T3; 2) myocyte culture was exposed to amiodarone (30–40 μg/ml) in the presence of T3 (10−5 M/ml); 3) myocyte culture was exposed to amiodarone (30–40 μg/ml) in the presence of three times the amount of T3 in experiment 2. The optimum concentrations of amiodarone for cell culture were determined by experimentation. The cells did not survive in concentrations higher than 40 μg/ml.

Controls basically included two cultures: 1) myocytes grown in the absence of amiodarone and T3 treatments; and 2) myocytes grown in the presence of T3 treatment and the absence of amiodarone. In addition, myosin from cultured neonatal rat cardiac myocytes was compared with myosin of neonatal and adult rat cardiac myocytes in vivo.

Myosin Isoform Profiles

The cultured myocytes with treatment of the drug and without T3 contained predominant isoform V1 (Figure 1). The V2 band was not as clear as those of isoforms V1 and V3. Although the expression of myosin isoform profiles in response to different doses of amiodarone was alike (Figure 1), the amount of myosin isoforms in cultured cardiac myocytes exposed to differential doses (30, 35, 40 μg/ml) of...
amiodarone was not alike. With the increased dose of the drug, there was an increase in $V_1$ content in cells grown without T3 (Table 1). The intact ventricles from 5-day neonatal rats without the treatment of amiodarone expressed predominant myosin isoform $V_1$, whereas the cultured myocytes without treatment of the drug and T3 (control culture 1) showed predominant isoform $V_3$ as observed in our previous studies.  

When cardiac myocytes in culture were exposed to amiodarone in the presence of added T3, the expression of myosin isoform $V_3$ was prevalent (Figure 2) or as strong as $V_1$ (Figure 3), unlike those of control myocytes grown in the absence of the drug and presence of added T3 (control culture 2). The control expressed predominant myosin isoform $V_1$. This observation conformed with those of Bagchi et al., who reported preferential synthesis of $V_3$ isomyosin over the control using an in vivo system in which endogenous thyroid hormones were present. In this experiment, the isomyosin content was also found to be drug dose dependent, showing an increase in the isomyosin $V_3$ content with increased dose. Cardiac myocytes exposed to amiodarone (30–40 μg/ml) in the presence of triple the usual dose of T3 expressed predominant isomyosin $V_1$ (Figure 2).

**DNA Synthesis in Heart Cells**

Because there is no significant difference in DNA synthesis between T3 treated and untreated myocytes, the results discussed do not include T3 treatment. DNA synthesis as determined by autoradiography of cardiac muscle cells grown in the presence or absence of amiodarone is presented in Figure 4. Initially, control cardiac myocytes grown in the absence of amiodarone showed approximately 15% labeled myocytes, whereas experimental myocytes grown in the presence of amiodarone exhibited 11% labeled myocytes after 24 hours of culture. With the continuation of the culture, however, the control cardiac myocytes exhibited a gradual rise in the number of labeled cells. The labeling index of control myocytes peaked on the third day, showing approximately 60% labeled myocytes. The labeling index declined to approximately 11% on the fifth day of culture (Figure 4). Cardiac myocytes exposed to amiodarone showed a sharp decline in labeling indexes after showing 11% labeled myocytes 24 hours after culture (Figure 4). The labeling of experimental myocytes ceased on the third day of culture, unlike that of the control culture, which showed labeled cells until termination of culture on the fifth day.

The profile of incorporation of [3H]TdR by heart cells as determined by the scintillation counter is presented in Figure 5. The incorporation of [3H]TdR into DNA of heart cells, which included cardiac muscle and nonmuscle cells without exposure to the drug, was significantly higher ($p > 0.001$) than that of the cells exposed to the drug. The results indi-
cated that the incorporation of [3H]Tdr per unit protein in the experimental cells declined sharply after 24 hours of incubation, showing minimal incorporation value on the terminal time point of the culture (Figure 5).

The cellular protein content at different time points of the culture is presented in Figure 6. The protein content in the control culture continued to increase throughout the culture period, whereas that of the experimental culture initially showed a slightly lower value than that of the control culture. Subsequently, the values for protein content in the drug-treated culture decreased significantly (p>0.001) compared with those of the control culture.

Ultrastructural Organization of Cardiac Myocytes

Cardiac myocytes in culture exposed to amiodarone were examined with the electron microscope to determine differentiation of their myofibrils and other cellular organelles during different time periods of culture. Myocytes after 24 hours of culture in the presence of amiodarone exhibited abundant myofibrils, mitochondria, free ribosomes, polysomes, glycogen, and sarcoplasmic reticulum similar to those of controls grown in the absence of amiodarone. Unlike the controls, myocytes contained scattered autophagic vacuoles and whorls of phospholipid. Mitochondria of the experimental myocytes often contained small, hollow, dense circular profiles absent in the controls (Figure 7). As the culture continued, well-organized myofibril content of the experimental myocytes decreased significantly, showing scattered segments of myofibrils and free myofilaments in the sarcoplasm of the cells after 3 days of culture (Figure 8). In addition, these myocytes contained abundant free ribosomes and polysomes, autophagic vacuoles, and whorls of phospholipid. Many mitochondria exhibited disrupted cristae. The whorls of phospholipid content increased in number after 6 days of culture, showing amorphous matrix in the central region of the whorl (Figure 9). The myofibril content and other cellular organelles of cardiac myocytes at this terminal point of culture did not differ significantly from those of 3-day-old culture myocytes. In contrast to the experimental myocytes, the control myocytes after 7 days of culture contained abundant organized myofibrils, mitochondria, ribosomes, glycogen, and sarcoplasmic reticulum (Figure 10).
FIGURE 6. Quantitation of cellular protein in neonatal heart cells grown in the presence or absence of amiodarone. The concentration of amiodarone was 30 μg/ml medium. Values are mean ± SD of six determinations at each time point.

Discussion

The present study shows that treatment with amiodarone produced two main types of results concerning the expression of myosin isoforms. When cardiac myocytes were exposed to amiodarone in the absence of added T₃ in the medium, myocytes expressed predominantly myosin isoform V₁, whereas addition of T₃ in the medium containing amiodarone showed a significant change in the expression of myosin isoforms.

FIGURE 7. Electron micrograph of a portion of cardiac muscle cell after 24 hours of culture in 30 μg amiodarone. The micrograph shows specifically abundant myofibrils and mitochondria along with dense circular profiles (Cp) in the mitochondria and a whorl of phospholipid (P) in the sarcoplasm. the preferential expression of isomyosin V1. It appears that amiodarone probably competes with T3 in T3-receptor sites and thus counteracts the influence of T3 on the expression of myosin isoform V1 during the treatment of cardiac myocytes with amiodarone in the presence of T3. This interpretation is in agreement with the idea that the intracellular inhibition of the conversion of T4 to T3 is not the ultimate mode of the action of the amiodarone effect on heart rate. It is thought that amiodarone interacts with T3 at its receptor or somewhere later along the pathway from the T3-receptor interaction to the final effect of T3 on the heart rate. Furthermore, the present interpretations agree with the previous findings that patients receiving amiodarone had a slowing heart rate, which gradually increased after withdrawal of the drug. This previous report conforms with the interpretation of the present data that the drug probably competes with T3 for receptor sites and thus inhibits the function of T3 in the myocardium. After withdrawal of the drug, the receptor sites become available only to T3, and the heart rate returns to its original state. Because amiodarone and T3 apparently are competing for the common receptor sites, the sites probably are distributed between these two extracellular agents, resulting in the formation of two pools of receptor-agent complexes, such as receptor-drug complex and receptor-hormone complex. It is possible that, as a result of the generation of two heterogeneous pools of receptor-agent complexes, there has been an alteration in the receptor function, which did not cause induction of the expression of isoform V1 although each of these agents (amiodarone and T3) independently can cause the expres-
FIGURE 9. Electron micrograph of a portion of experimental cardiac myocyte after 6 days of culture showing specifically a large number of whorls of phospholipid (P), scanty myofibrils (Mf), autophagic vacuole (Av), and damaged mitochondria (Dm). Magnification, ×15,030.

The previous in vivo studies concerning antiarrhythmic activity of amiodarone suggested that amiodarone inhibits the peripheral conversion of T₄ to T₃ and may block the metabolic action of thyroid hormone in bringing about the reduced heart rate. It is also reported that the effect of amiodarone was observed despite normal serum T₃ and thyroid-stimulating hormone and elevated T₄ concentrations, which most likely are due to inhibition of peripheral 5′-deiodinase rather than the effect of iodine released from the drug. The present studies show that amiodarone has a direct effect on the expression of myosin isoforms of cardiac muscle cells in culture. The preferential expression of myosin isoform V₁ by cardiac myocytes exposed to amiodarone in the presence of physiological concentration of T₃ results in reduced contractility owing to its lower ATPase activity. This effect probably includes the reduction of V₃. Surprisingly, cardiac myocytes grown in the absence of added T₃ and in the presence of amiodarone expressed predominant myosin isoform V₁ in contrast to the control, which expressed predominant isomyosin V₃. The control myocytes were grown in the media devoid of amiodarone. This opposite effect of amiodarone as compared with the above finding is not fully understood. Amiodarone under this experimental condition does not compete much for T₃ receptors because of the lack of added T₃ in the medium and probably occupies most of the T₃-receptor sites for drug actions. This finding appears to imply an analogous role of this drug to that of T₃ in preferentially promoting the expression of isomyosin V₁ rather than V₃. These observations may show a positive implication on the findings that show the occurrence of both hypo- and hyperthyroidism in some patients treated with amiodarone. 

The previous in vivo studies concerning antiarrhythmic activity of amiodarone suggested that amiodarone inhibits the peripheral conversion of T₄ to T₃ and may block the metabolic action of thyroid hormone in bringing about the reduced heart rate. It is also reported that the effect of amiodarone was observed despite normal serum T₃ and thyroid-stimulating hormone and elevated T₄ concentrations, which most likely are due to inhibition of peripheral 5′-deiodinase rather than the effect of iodine released from the drug. The present studies show that amiodarone has a direct effect on the expression of myosin isoforms of cardiac muscle cells in culture. The preferential expression of myosin isoform V₁ by cardiac myocytes exposed to amiodarone in the presence of physiological concentration of T₃ results in reduced contractility owing to its lower ATPase activity. This effect probably includes the reduction of V₃. Surprisingly, cardiac myocytes grown in the absence of added T₃ and in the presence of amiodarone expressed predominant myosin isoform V₁ in contrast to the control, which expressed predominant isomyosin V₃. The control myocytes were grown in the media devoid of amiodarone. This opposite effect of amiodarone as compared with the above finding is not fully understood. Amiodarone under this experimental condition does not compete much for T₃ receptors because of the lack of added T₃ in the medium and probably occupies most of the T₃-receptor sites for drug actions. This finding appears to imply an analogous role of this drug to that of T₃ in preferentially promoting the expression of isomyosin V₁ rather than V₃. These observations may show a positive implication on the findings that show the occurrence of both hypo- and hyperthyroidism in some patients treated with amiodarone.
in oxygen demand on cardiac muscle cells and thus may cause the antianginal effect of the drug. Although a dose-dependent response of amiodarone was observed, the dose higher than 40 μg/ml killed the myocytes, showing its toxic effect on the cells. T₃ above the physiological concentration reversed the expression of myosin isoform caused by amiodarone, showing an expression of predominant isoform V₁. This observation agrees with that of in vivo studies and indicates that amiodarone causes a hypothyroid-like state in the myocardium. In the past, therapeutic induction of hypothyroidism helped the treatment of intractable angina.²⁶ However, it is not known whether antithyroid activity of amiodarone causes the antiarrhythmic effect of the drug.

Amiodarone has significant influences on DNA synthesis, cellular protein content, differentiation, and survival of cardiac myocytes in culture. DNA synthesis in cardiac myocytes is inhibited and subsequently stopped by amiodarone after 3 days of culture in contrast to the control, which attained a peak in labeling index with approximately 60% labeled cardiac myocytes after 3 days of culture. The labeling index of the control cardiac myocytes gradually declined, showing 11% labeled myocytes after the terminal time point of culture on the fifth day. The data on cellular protein content in drug-treated cultures showed significant lower values compared with those of control cultures, which showed continuous increase in protein concentration throughout the culture period. These observations show that this drug has a strong inhibitory effect on cardiac cell proliferation and protein synthesis, and thereby the growth of the myocardium. The lower protein content in the experimental culture appears to be a reflection of the lower cell proliferation rate, of reduced protein synthesis, and, to a certain extent, of cell degradation. The effect of amiodarone on the differentiation of myofibrils and cellular organelles as observed by electron microscopy showed that this drug has retarding and degrading effects on these structures. Initially, cardiac myocytes contained
abundant, well-differentiated myofibrils and cellular organelles, but as the culture continued, myofibrils were disassembled, showing scattered irregular segments of myofibrils and free myofilaments in the sarcoplasm. The myocytes contained many degraded mitochondria and autophagic vacuoles containing degraded cellular materials. A considerable number of degraded cardiac cell bodies were observed in late culture. These cell bodies were indicative of cell deterioration and death. The overall effect of this drug on the ultrastructure of cardiac cells is not conducive to the maintenance of cellular structures needed for proper functioning.

These studies have demonstrated that amiodarone has a direct influence on the cardiac myocytes for expression of myosin isoforms. Moreover, this drug has an inhibitory effect on the growth and differentiation of cardiac myocytes. The ultrastructural studies suggest that prolonged use of this drug can damage the myocardium.
